livered an important lecture on the advantages of circumcision. The most obvious advantage, he said, was cleanliness. This is important in childhood. In adults the habit of withdrawing the skin and washing the glans has usually been learned, though it is not practised sufficiently. In children it is not, as a rule, attempted; most boys would regard the attempt as indecent, and in many paraphymosis would result. Moreover, the practice would be injurious to morals; yet the accumulation of smegma and its decomposition is a source of annoyance and irritation to many boys. Further, any irritation of the glans penis is liable to produce reflex excitement of a character to be avoided. In middle life to many the possession of a prepuce is a source of more or less habitual annoyance. Seborrhea, balanitis, and herpes are common. As old age comes on the danger of cancer to those who suffer from phymosis is considerable. Similarly, circumcision tends to prevent syphilis. Mr. Hutchinson has found that, while gonorrhea is quite as common among Jews as among Christians, syphilis is much less so. This shows that it is not on morality that the comparative immunity of Jews to syphilis depends. The only possible explanation is the absence of the prepuce. It would be difficult to contrive an appendage more likely to facilitate the implantation of the syphilitic virus than the prepuce. No measure which has ever been proposed for the prevention of syphilis is as efficient as circumcision. Unlike other measures, such as the inspection of prostitutes, it has no collateral influence prejudicial to morality, nor does it offend the sense of decency. Finally, circumcision probably tends to increase the power of sexual control. The only physiological advantage which the prepuce can be supposed to confer is that of maintaining the penis in a condition susceptible to more acute sensation than would otherwise exist. It may increase the pleasure of coition and the impulse to it; but these are advantages which in the present state of society can well be spared. If in their loss increase in sexual control should result, one should be thankful.

CEPHALOTRIPSY OF THE AFTERCOMING HEAD—UTERINE FIBROIDS—VAGINAL HYSTERECTOMY—POSTPARTUM HEMORRHAGE—TOXIC LARYNGEAL PARALYSIS—CAMP SANITATION—SMALL-BORE RIFLE WOUNDS.

J. H. Targett, at the British Medical Association meeting, held at Ipswich July 31 and August 1, 2 and 3, 1900, recommended as the sites for perforation of the aftercoming head the region behind the ear, and the suboccipital space. This operation is not infrequently attended by much difficulty, especially if the head is retained above the brim of a contracted pelvis and the lower segment of the uterus is imperfectly dilated. Perforation through the mouth then becomes almost impossible, and even the suboccipital space may be hard to reach. If the latter route is chosen the aperture is liable to be directed too much toward the foramen magnum, so that the exit of brain matter is impeded. Moreover the cerebellar fossa is alone opened, the larger part of the cranial cavity being practically shut off by the tentorium. Perforation behind the ear meets this objection, but it is important to work well above the root of the mastoid process, and this site is higher and more difficult to reach than the suboccipital region, at least in the cases of marked pelvic contraction. To avoid laceration of the cervix one blade of the cephalotribe should be passed into the aperture made by the perforator while the other blade is adapted to the exterior of the head. Experiments have shown that the best grip is obtained by inserting one blade into a suboccipital perforation, while the opposite blade is applied over the face. Assuming that the woman is in the lateral obstetric position and that the pelvis is flattened, it will be most advantageous to have the long axis of the head engaging the transverse diameter of the brim with the occiput uppermost, and if the occiput happens to be forward the head should be gently rotated in the required direction. The trunk must then be drawn forward as far as possible to give room for the application of the cephalotribe posteriorly. The advantages of this method are that the head is seized by its base in the chief anteroposterior diameter, that the most rigid part of the skull is thus effectually crushed or strongly flexed on the spine, that a very firm grip is obtained, and, lastly, that it is easier to apply the cephalotribe.

Some ten or twelve years ago Dr. Donald, of Manchester, published an able paper on the methods of craniotomy for cases of severe pelvic contraction. He recommended a preliminary podalic version and extraction of the body, then perforation through the roof of the mouth, and, finally, crushing and extraction of the aftercoming head. The advantages claimed were that the base of the skull was thoroughly broken up and that the head could be easily rotated into the best diameter and well fixed by traction. This advice is quoted by most writers on obstetrics, but the practice is not carried out in any of the large London maternities. Version after cephalotripsy is very rarely adopted.

Alban Doran said that the first question with relation to the natural history of the uterine fibroid is its pathology. Microscopically neither a fibroma nor a myoma, it partakes of the characters of each with those of the latter predominating, and hence approaches the uterine tissue more or less closely. This is affected by ergot, hence ergot has been used for fibroids, acting then because the structure is rather uterine than myomatous. Although nobody would think of curing a fibroma of the periosteum with drugs,

ergot has been of much value in these uterine neoplasms. But the association of them with cardiac lesions often contraindicates its employment. A second important factor is the relation between the ovaries and these tumors. Notwithstanding the long painstaking research in Germany, no one can claim to understand all about normal menstruation nor much about the relation the ovary has on the growth of fibroids. But clinical experience shows us that in some cases the removal of both ovaries is followed by a reduction in the size of the tumor. Failure of this result has shown merely that it is not an essential sequel and leaves us in doubt as to whether all of the ovarian tissue has been ablated. The ovarian ligaments often contain sufficient gland-tissue to account for a certain number of these failures. In fact the speaker recalled successes when gland-substance was known to have been unavoidably left behind. Another fact associated with fibroids is bleeding. We do not understand why in many there is much hemorrhage, while in many more there is none. But until menorrhagia and metrorrhagia are themselves better understood independently of fibroids little surprise need be felt. The question of the rate of growth of these offenders is never surely answered, as all degrees are encountered. Upon menopause their effect seems one of delay, often by several years; while they do not perhaps really cease to grow, they rarely give trouble after the climacteric. As to treatment, enucleation of the small fibroid, hysterectomy where this cannot be done, and electricity in a few cases sum up the matter. Medicines, except for some of the symptoms, do not do much good.

M. A. D. Scharlieb stated the limitations of vaginal hysterectomy to be in cancerous disease (1) local extension of the process beyond the uterus; (2) infection of the pelvic, iliac lumbar and other glands; (3) metastases in distant organs, as lungs and liver; (4) concomitant disease of the body as diabetes and nephritis. Unless respect is had for these points the statistics of the operation will suffer and the ultimate results in given cases will not be satisfactory. Duty to the patient, to ourselves and to the operation demands careful survey of all these considerations. Of thirty-five cases tabulated from the records of the New Hospital for Women in London four died within one month after the operations, one of kidney disease, one of shock from a too long and difficult operation, and two of sepsis. Due review of all conditions would probably have avoided each.

John W. Byers classes all postpartum bleeding as of three kinds, due either to uterine atony with patent vessels at the placental site or to wounds of the parts of the parturient canal without any uterine inertia, or to both combined. The onset of a severe hemorrhage may be expected (1) when there is a history of it during previous confinement; (2) with uterine relaxation due to too frequent childbearing; (3) with ill health due to too little exercise and overfeeding; (4) with great mental depression, as at the death of the husband; (5) with the circulatory excitement late in pregnancy; (6) with overdistention of the uterus in twins and hydramnios; (7) with tumors of the uterus preventing contraction; (8) elderly primiparæ; (9) preexisting metritis; (10) albuminuria; (11) short, jerky pains, with intervals between them longer than the pains themselves; (12) short, rapid pulse, rather jerky and of low tension. The prophylaxis which should be adopted in all deliveries consists in the proper management of the third stage of labor and in the principle never to deliver in the absence of true uterine pains. The placental stage of labor consists of two factors, the separation and the expulsion of the afterbirth. Nature herself usually performs the separation perfectly and often adds complete expulsion, but the latter is the step in which the accoucheur is called upon to render assistance. The signs of the freeing of the placenta naturally are so definite that every practitioner should know them and be in that way prepared to avoid attempting to separate them himself directly risking retention of membranes, sepsis and postpartum hemorrhage. The details of the placental period of delivery may be reviewed thus: As soon as the head of the child is born, the left hand of the accoucheur grasps the fundus, the ulnar border being apposed to the vertebral column of the mother, and during the balance of the delivery the hand never leaves the uterine fundus. If the child is asphyxiated, or for other reason, the nurse may follow the fundus down. The hand remains in contact with the uterus throughout in order to perceive the separation of the placenta, but no massage of the organ should be indulged in at these periods. The separation of the placenta is shown by these indubitable signs: (1) A sudden rising up of the uterus which may have been largely in the cavity of the pelvis; (2) a swelling in the lower uterine segment bulging over the pubic symphysis much like a distended bladder, with which it has often been confused; (3) greater mobility of the uterus; (4) expulsion of a few more inches of the cord, shown by the advance of the ligature which, after a slight pulling on the cord to straighten it in the vagina, was placed close to the vulva. After the separation is thus manifest, expulsion occurs naturally or by pressure on the fundus after Credé's method. Examination of the afterbirth should now be made for fragments of it or of its membranes or for placenta succenturiata retained. The massage of the fundus may now be begun, when the cavity is manifestly empty. The other important step in delivery is never to empty the uterus in the absence of pains, but rather by sedatives secure rest for the mother and wait for the contractions to appear again. When from history and other facts hemorrhage is to be expected, the prophylaxis to be maintained is rigid and sensible hygiene throughout pregnancy and slow, careful

delivery. Chloride of calcium, thrice daily, for a few weeks before confinement may be of value. The treatment of the actual hemorrhage is foremost to have at hand all the necessaries for this often unexpected trouble. The means are uterine massage, copious, hot, sterile-water intrauterine injections, cleaning of the cavity of membrane and placental shreds, bimanual compression, and firm gauze tamponade. The Vienna school recommends drawing the uterus far down into the vagina or even everting it, in order to close the sinuses and kink the arteries. Injections of styptics, especially of perchloride of iron, are not safe. Hemorrhage from tears of the parturient canal requires suture, ligature and tamponing according to circumstances. The after-treatment in all cases is stimulation, intravenous infusion of normal salt solution, subcutaneous injections and high rectal enemata of the same. Later come good food and tonics.

P. W. Williams recited the common causes of toxic paralysis of the larynx as being grouped, either as infective neuritis commonly occurring in the course of a diphtheria, less frequently in typhus fever, typhoid fever, scarlatina, morbilli, influenza, rheumatism, tuberculosis, syphilis, cholera and malaria, or as tonic neuritis most commonly due to lead-poisoning, also ascribed to arsenic, copper, antimony, phosphorus, alcohol, atropine and morphine. The treatment of these conditions consists in the proper management of the original infectious disease and of elimination of any known poison. Locally galvanism and faradism and if possible strychnine, otherwise strychnine systemically, intubation or tracheotomy to relieve dyspnea due to bilateral abductor paralysis, especially common in diphtheria and typhoid fever.

Major James stated, in discussing the subject of sanitation in camps, that the conditions of camps are so various and depend upon so many circumstances that there are few points of detail that apply to all. The objects to be kept in view are: (1) Protection of troops from weather and climate. (2) Feeding them, and preventing disease communicated by food. (3) Disposal of excreta and refuse. (4) Prevention of local and endemic disease. (5) Prevention of spread of communicable diseases. The possibility of properly carrying out sanitation must depend upon several circumstances: (1) Choice of site; whether this is governed primarily by strategic or hygienic considerations, and whether the first consideration is to make it a defensible or healthy camp. (2) Whether the camp is a standing or temporary one. (3) Whether the supplies can be obtained locally, wholly or in part, or whether the transport is sufficient to make available plenty of food, tentage, and stores. (4) The climate. In any case the art of camping is one which depends upon ingenuity, and the longer troops are in the field the better accustomed they become to making themselves comfortable. The following remarks apply to camps where some stores are locally obtainable, and the class of country—China and South Africa—where British troops are now and may be shortly engaged. The primary essentials for properly carrying out measures of sanitation in camp are discipline and intelligence among occupants, and an efficient and well-instructed sanitary staff. It is to be remembered that while troops are doing hard work under exciting circumstances they are generally fairly healthy, and that it is when they are idle or when the excitement is passing that they become sick. Water supply is one of the most important things to supervise, and most of the commonest camp pests in the shape of enteric fever, dysentery perhaps, and cholera, are waterborne. The distribution must be as closely watched as the origin, and this in camp is a great difficulty. When men are thirsty they will drink anything and anywhere. He believes something could be done by education to restrain a man at ordinary times, but when the weather is hot and water scarce reason has to give way to impulse. If, however, water is plentiful and good and obtained from a stream, a spot above the camp should be marked for drinking; lower down for horses, and lower for bathing and washing clothes. The point of obtaining the drinking water should be policed, and the stream above as well as the area draining into it put out of bounds.

Clinton Dent said that, broadly speaking, in the South African campaign bullet wounds had done extremely well. Remarkable recoveries were numerous and many badly wounded had been able to return to duty. Amputations were proportionately very few. These results were doubtless due to the small-bore, high-velocity ball and the great advance in field and base surgery.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held June 5, 1900.

The President, Frederick Peterson, M.D., in the Chair.

Exophthalmic Goiter.—Dr. Mary Putnam Jacobi presented a case of this disease treated by intestinal antiseptics. B. D., was first seen February 8, 1899, aged twenty-two years. She had been well until the age of twenty, when she began to work at a shop for making infants' clothing. She worked from eight until five on button-holes and feather-stitching. She began to suffer much from constipation, relieved by frequent purgation with licorice powder. At the end of a year menstruation ceased, *i. e.*, in July, 1897. Six months later the eyeballs began to be prominent; at same time there developed flushings of heat all over body, palpitations, headache and weakness, tremor of hands and feet, especially on rising in morning, frequent distress in stomach. In

the summer of 1898 constipation was replaced by chronic diarrhea. In February of this year she had a severe attack of diphtheria and was cared for at Mt. Sinai Hospital. On recovery from this she felt much better for a time. The thyroid gland was only moderately enlarged and appeared to be slightly larger in the morning at the time the tremor and diarrhea occurred. There was marked accentuation of both cardiac sounds over tricuspid, but not at mitral; no murmurs at heart, but systolic murmur at carotid; pulse 120; respiration 24. Sphygmogram regular, rapid, with normal dicrotism. Complaint of constant aching in upper dorsal region between shoulder-blades, region of columns of Clarke. An attempt at a complete milk diet rendered the patient very weak and miserable and increased the tachycardia to a point where the pulse could not be counted. The urine was examined by Bouchard's method twice during the winter, once in February and again in March. On the first occasion the toxic coefficient was .579, on the second, .712. The patient had been treated by various nervous and vascular tonics before she came under observation without material benefit. The ordinary line of medication was abandoned altogether and disinfection of the intestinal canal was practised. Various disinfectants were used at different times during a long period, bismuth salicylate and betanaphtol, associated with a daily flushing of the colon with two quarts of water. Under this treatment, especially the colon flushings, the diarrhea was arrested, the patient grew steadily stronger and the menstruation returned on April 15, 1899, after an amenorrhea of twenty-two months. The week before this appeared a third examination of the urine gave a urotoxic coefficient of 1.426, nearly double the toxicity found in March. For eleven months the pulse remained at 120. On April 21st the patient was feeling very weak, with much headache and anorexia, and the urotoxic coefficient was .388, the only time at which it was subnormal or any other than excessive. On March 27th, after an experiment with thymus gland, the coefficient was 1.662; menstruation occurred three days later. After this it was absent until January, 1900, when it returned and has occurred regularly ever since. The last urinary examination was made May 22, 1900, and the coefficient was then nearly normal, being .432. The pulse remained at 120 or over with scarcely an exception for eleven months, when, on January 24th, it became 100 and did not change in spite of an attack of diarrhea and insomnia. On February 7, 1900, the medication was changed to salicylate of soda of which from 60 to 80 grains a day were given. After ten days the pulse was 93; ten days later, 92; on April 4th, 90, June 4th, 90. An intercurrent attack of diphtheria, treated at home by muriate of iron, had the effect of lowering the pulse to 90.

In the discussion Dr. E. D. Fisher said that this case shows a very vascular condition of the thyroid gland. He did not absolutely agree with Dr. Jacobi in the use of intestinal antiseptics. He had found the continued use of strophanthin successful. That treatment might be carried out in a case of this kind. Dr. Wm. H. Porter treated two cases of a similar nature at his clinic by antisepsis of the alimentary canal, to prevent toxic infection, with better results than had been obtained under other treatment for that class of cases. Dr. Wm. H. Caswell said that glycero-phosphate of soda, 15 grains three times a day, had been efficacious in one case under treatment. The pulse has fallen from 130 or 140 to 84 or 88 and remained so for the past two months. All constitutional symptoms were very much improved, although the exophthalmus had not disappeared, nor was there any decrease in the size of the thyroid. The patient was better and was still doing well.

Dr. Jacobi spoke of the question of the urotoxic coefficient, although he said he had not paid any systematic attention to it. He had noted that when the urotoxic coefficient was in excess of normal, the patient was better. On one occasion it fell below normal and the patient was decidedly weaker, with symptoms of more constitutional poisoning, confirming the idea that poison circulating in the blood and excess of urine toxicity coexist with the effort of the organism to throw it out. When the toxicity is high, the patient is better; when subnormal, the patient is worse. This is approximate.

Congenital Hydrocephalus, Non-Inflammatory Type.—This case was presented by Dr. Joseph Fraenkel. He thought it worth while to bring the case as it seems unusual in its clinical pathology and he was in doubt as to the best diagnosis. The child, twenty-six months old, was born at full time without difficulties. Father aged thirty-six, mother thirty, Russian Hebrews, perfectly free from taint. Three living children perfectly well. One miscarriage prior to birth of this child. Immediately after birth it was noticed that the child was abnormal. It did not hold its head up and gave no evidences of mind or brain development. The symptoms became more accentuated. At no time has it walked, talked or shown any signs of mental vigor. Obstinate constipation has existed since birth. All examinations have given a negative result. There are no evidences on the skeleton pointing to rachitis. The upper and lower extremities are rigid; permanently contractured, but the contracture can be overcome and the reflexes are present. No ankylosis; reflexes not exaggerated as would be expected. The child vomits, and has had three or four general convulsions. After the last one the child lost its voice for three or four days. Sensation in so far as it can be examined is negative. The head is somewhat large, 46 anthropometers in circumference, although not so large as in hydrocephalic infants usually. The fontanels are not closed. Child was put on iodide of potassium and syrup and iodide of iron and was thought to improve, but objective examination showed no improvement.

Dr. Fisher agreed with Dr. Fraenkel's diagnosis of hydrocephalus, non-inflammatory type, congenital. One case which he had seen showed a congenital condition of interference of the circulation through the fontanels to the spinal cord. Dr. Jacobi asked if there might not be a correlation between the small head and the severity of the symptoms. For some reason the skull had not yielded, thus causing greater intercranial pressure than in ordinary cases where the skull is large and necessarily the pressure less. Dr. Lewis A. Connor said that the question of increased intercranial pressure can be determined by puncturing and the use of the monometer to measure resistance. A monometer may be improvised by using a bent glass tube with a short horizontal arm and a long perpendicular one, and attaching it by a piece of rubber tubing to the cranium. Dr. Peterson said that the fontanels being open would seem to show that there is not unusually great pressure. It does not look like congenital hydrocephalus. In that disease there should be an unusual growth of the head. He had seen this rigidity resulting from basilar hemorrhage occurring during labor.

Multiple Neuritis Following Pneumonia.—Dr. Connor presented this case. The patient, male, forty-one years of age, came to the Hudson Street Hospital on November 7th with a lobar pneumonia of five days' standing, with typical history and physical signs. The consolidation involved left upper and lower lobes and ran a normal course up to the point of deflorescence. Instead of clearing up at the end of the seventh or ninth day, the temperature dropped and the consolidation remained, presenting the ordinary picture of delayed resolution, lasting two weeks beyond the allotted period. During that time the patient gave no evidence of any other trouble. Just at the end of this period of consolidation, three weeks from the beginning of the attack of pneumonia, it was noticed that his legs were weak and that he had some discomfort in moving them and the left arm extensors were paretic. In the course of a week the following picture was developed: Extensive, almost complete paresis of the extensors of the leg, tibialis group and peroneal muscles, extensors of the left arm and slight loss of power in the right arm. No anesthesia. Some numbness of the tips of the fingers and an area of hyperesthesia over the crest of the iliæ on both sides. Almost no pain except girdle sensation. Tenderness over the calves of legs and arms very slight. Diaphragm was not moving properly and in about a week from the beginning of symptoms of paralysis, there was complete loss of function of the diaphragm, with either forced or natural respiration. It was a severe multiple neuritis which ran a course of five weeks before any improvement could be noticed. He can now walk about and has recovered very largely the use of his left hand. It was six weeks from time of disappearance of function in the diaphragm before the first contraction could be recognized. So severe a neuritis is very unusual in lobar pneumonia. It is recognized as a possible complication, but an unusual one, and in those cases personally observed the neuritis has been local or else of a mild type. The man's history is good as far as syphilis or tuberculosis is concerned. He has been accustomed to drink three or four glasses of beer or ale in the course of the day and, two or three times a week, a glass of whiskey. The picture has not been that of alcoholic neuritis, nor were the sensory symptoms less marked than they usually are in these cases.

Dr. Cunningham asked what was the state of the pulse during this attack. Was the vagus involved? Dr. Connor replied that it had remained normal. Only the pupils were involved. Dr. Cunningham said that in alcoholic neuritis the vagus invariably is affected several days before the diaphragm is involved.

Dr. Jacobi asked if it were supposed that there was any infection by continuity of inflammation from leg to the diaphragm, affecting the phrenic nerves. Dr. Connor said his idea was that it was purely a matter of toxemia, delayed resolution, long-continued condition of consolidation with the growth of the specific bacterium. This was a case of toxemia sufficient to produce this result, taken in conjunction with the damaged condition of the nerves from his alcoholic habit.

Dr. Peterson said that Dr. Connor's case was quite unusual; it certainly was one of simple multiple neuritis following pneumonia. The moderate alcoholism might not have been sufficient to produce neuritis, but the added toxic condition of the blood caused by the pneumonia was sufficient to bring it about.

Progressive Muscular Atrophy.—Dr. Caswell presented the case of a young woman, twenty-one years of age, who came to the Vanderbilt Clinic seeking treatment for weakness in the hands. She is a maker of artificial flowers. Five or six months previously her hands began to fail and she could not work so easily as before. On investigation it was found that from the time she was a young girl she had had difficulty in closing her eyes, and she did not smile and use her lips and mouth as other children did. She was not conscious of this and only complained for the past few months that her hands failed at work. Examination showed a case which in almost every particular conforms to the type of primary progressive dystrophy described by Landouzy-Dejerine—beginning in the face with no hypertrophy, the atrophy showing later in the upper extremities. The lower extremities were fairly well developed for a thin girl. The arms from elbows to fingers were not atrophied. From elbows to shoulders there was marked atrophy on both sides. Pectoral muscles about the triangles of the neck were decidedly wasted and fallen away. When the arms were turned backward the superior scapulæ going into the triangles of the neck can be seen on both sides; when the hands are put forward, the scapulæ are winged. This is due to the atrophy and weakness of the

lower portion of the trapezius and deltoid. The face is myopathic. The onset of this disease is very insidious. Until the patient notices something which interferes with daily employment or manual labor he does not seek treatment.

Dr. Fraenkel knew of a case which has existed for any number of years. It has been stationary for seven or eight years. Some additional symptomological movement may excite it, and the advance of the disease will be brought to the attention of the physician. One may find slight indication of paralysis of the face; the disease stops there without fresh clinical manifestations.

Dr. Caswell spoke of another case of this kind at the Vanderbilt Clinic which had progressed very slowly during the past five or six years. The changes in the face were very slight, but it was gradually growing worse; the patient does not notice it, however.

Dr. Peterson said that he did consider the Landouzy-Dejerine type very rare up to two years ago, rarer than the Erb juvenile form. Within the past two years he had seen four cases of perfectly typical syndromes. The history is usually indefinite except as to the eyes. Patients have never remembered being able to close the eyes. This led him to suggest that some cases occasionally met with, of bilateral lagophthalmus, might turn out to be this disease. Several years ago he thought this form a variation of the Erb juvenile type. Now he thinks it is a different syndrome with a different pathological basis.

Progressive Muscular Atrophy.—Dr. Leopold Stieglitz presented a man, thirty-three years of age, born in Germany, who came to this country four years ago; father died of heart disease; mother, one brother and four sisters living; knows of no similar trouble among them. He cannot state exactly when his present trouble began. Has noticed for some years weakness in the legs, inability to lift them properly from the ground, difficulty in walking, and that he tired easily. This condition became steadily worse. The patient was seen four years ago at Mt. Sinai Dispensary. Upon examination there was very profound atrophy of the peroneal group of muscles in both legs, no disturbance of sense, slight signs of reaction of degeneration. The case was entered as one of the peroneal type of progressive muscular atrophy. Last February the patient returned to the dispensary complaining of weakness in the arms. Examination then showed that in addition to the affection in the legs there was a very pronounced typical condition of progressive muscular dystrophy of the body. The atrophy involved also the gastrocnemius muscle of the calf and to a certain extent the muscles of the thighs. On both sides there was atrophy of the pectoral, hypertrophy of the deltoids on both sides, wasting away of the upper arms, typical drop-foot and atrophy of the lower extremities. The diagnosis was peroneal and juvenile types of progressive muscular atrophy or dystrophy. The electrical reactions, however, did not correspond to those one would expect in a case of this kind. They were normal in the upper extremities, absent entirely in the lower. The patient has winged scapulæ, protruding abdomen, kyphosis of the back; all indicative of progressive muscular dystrophy.

Dr. Fraenkel said that three types of dystrophy are shown in this patient. The remarkable feature is the absence of any heredity. This condition is unusual at so late an age. He is very flabby.

Dr. Peterson agreed with Dr. Stieglitz that it was the juvenile type. He thought that there was a marked distinction between the juvenile and the Charcot-Marie-Tooth forms. The two syndromes are not alike. One peculiarity is that the legs below the knees are affected. In this patient the thighs are affected as in the Erb-juvenile form. The pathology is the same in this case. It is not apparent why in the Erb-juvenile form other muscles than those of the shoulder girdle are not involved.

Dr. Stieglitz spoke of the unusual feature of the commencement of the disease in the lower extremities. He had looked up a number of histories and could find nothing that exactly corresponded with this case. The involvement of the lower legs was not so unusual, and in this case simply the muscles below the thigh sequence were involved. Atrophy of the muscles of the thigh is common in progressive muscular dystrophy. He thought that one should distinguish between the Charcot-Marie-Tooth and Landouzy-Dejerine types on account of the difference in pathology; one is a disease of the trunk nerve of the cord. The Landouzy-Dejerine type is purely myotropic. On that account one should not try to connect the two syndromes. The family history should be carefully investigated, for the statements of the patient are sometimes misleading.

Hereditary Cerebellar Ataxia.—Dr. M. Mailhouse presented this case. The patient, F. F., was admitted to the New Haven Hospital January 13, 1900, with the following history: Age, thirty-two years; single; birthplace, United States; occupation, postal clerk; father and mother living and well; has five sisters living all in good health. One sister died of pulmonary tuberculosis and another died in infancy of causes not stated. Mother's mother also died of pulmonary tuberculosis. A sister of his mother is at present an inmate of the Connecticut Asylum for Insane. Mother and father have had muscular rheumatism. Patient had scarlet fever and diphtheria at fifteen years of age. When a boy had rheumatism of mild degree. In 1887 had sunstroke which left him confined to his bed. No syphilis, alcoholism or tuberculosis. The history taken on his admission to the hospital states that the patient first noticed in 1887 a dragging of his toes on walking and that his shoes curled up and were worn at the toes; did not walk with a stamping gait and could direct his feet anywhere without trouble. Legs did not cross on walking.

On closing his eyes while standing was unable to keep his balance. Had no pain in the legs but considerable backache. Then his hands began to tremble (1888) and his legs shook on walking. These symptoms increased and he had to use two canes in walking in 1888; in 1889 he used a crutch and one cane, and in 1890, two crutches. Has lost 57 pounds in weight within the past ten years. Has headache off and on, not severe. He also states that when twenty-one years of age he noticed an inability to run; he could walk but when he ran his legs got mixed up as though they were playing cross tag with one another. For past four or five years erections have been incomplete, and one time had frequent urination.

Status Præsens.—A man above medium height, of good frame, but somewhat emaciated. A striking feature as he stands supported by his two crutches is the nodding tremor of his head which is aggravated by walking. There is marked asymmetry of the head, a flattening of the occiput and pronounced sloping of the forehead with considerable flattening over the left parietal region. There is some facial asymmetry also as evidenced by a greater prominence of the right supraorbital arch than of the left. The nose is directed toward the right and the left palpebral fissure is smaller than the right. His gait is markedly ataxic, but he is able to get about fairly well on a level with the aid of crutches, but loses his balance readily on attempting to ascend a step. There is absolutely no muscular weakness in his legs. The knee-jerks are present, but not exaggerated. There is no ankle-clonus. The Romberg symptom is present and he is supported with difficulty when he stands with closed eyes. There is no impairment of sensation of any one of the forms, from head to toe. His movements are quickly performed, jerky, as is observed when he attempts to touch the tip of his nose with the index finger, the eyes being closed. The ataxia of the upper extremities is much less evident than in the legs. His speech is noticeably affected, but changes, being at times scanning or staccato and at others characterized by indecision and unsteadiness in the muscles of vocal expression; it is decidedly an ataxic speech. The pupils react neither to light nor accommodation. There is marked lateral nystagmus and on looking upward a rotatory mystagmus; when the eyes are at rest there is no oscillation. There are no contractures and no scoliosis. The grasp of the hands is strong and the muscles of the arms show no loss of power. The pectoral muscles are wasted, otherwise no atrophies are present. There is no optic atrophy and no limitation of the visual fields, but he is myopic, requiring a lens of seven diopters. The superficial reflexes are present, the plantor being very active. Urine presents no abnormality. The handwriting is like that of a tabetic. A review of the symptoms reveals the marked ataxia of the whole muscular system without any paralytic phenomena. The case resembles Friedreich's ataxia in its mode of development and general appearance, but differs from the typical disease in its later onset, in retaining the knee-jerks, in the late and mild affection of the arms, in the loss of the ocular reflexes, and in the absence of contractures or paralysis; the man has been afflicted twelve years and there is no paralysis or contracture present. The question might arise as to its being a multiple sclerosis, but this affection can be ruled out by the mode of onset, it being ataxic rather than paraplegic, by the normal reflexes and sensory phenomena and the absence of intention tremor. Furthermore, the long duration of the illness without any paralyses, ocular or corporal, militates against such a diagnosis. The case was presented not as an argument in favor of the type of hereditary cerebellar ataxia, but rather as a clinical example of ataxia presenting such a symptom-complex..

Dr. Caswell said that in the form of ataxia described, the fundus is generally affected; there is more or less neuritis, the knee-jerks are increased, and in this way discrimination is made between cerebellar and ordinary ataxia.

Dr. Fisher thought the sunstroke may have had something to do with the condition. He remembered a case of sunstroke followed by symptoms of this type, resembling compound or multiple sclerosis, but not conforming strictly to either. Taking that as an etiological factor, there is ordinarily some meningitis, some change affecting the cortex of the brain leading to the ataxic symptoms. Also ataxia, incoordination of the muscles, spastic condition of the patient—a degenerative condition secondary to some such lesion as that produced by sunstroke.

Dr. Peterson had examined the man before the meeting and thought that the diagnosis lay between multiple sclerosis and cerebellar hereditary ataxia. He was inclined to think that Dr. Mailhouse is right in his diagnosis of cerebellar-hereditary ataxia on account of the pupilary condition—no reaction to light—and because he has more of an ataxia than tremor of the ordinary sclerosis type.

Dr. Wm. B. Pritchard asked if there was anything of note in the subjective history of this case with reference to vision, hearing, or persistence of vertigo or headache that added to the data. Dr. Mailhouse said there were no subjective symptoms at all, except backache and difficulty in manipulating the legs. He is strongly myoptic without optical strain.

Raynaud's Disease of Gangrenous Type.—Dr. Wm. H. Porter presented this case. The patient came to this country some years ago; for a year or so was a hod-carrier, then went into an iron foundry where he has since worked. Has a very pronounced alcoholic habit, uses tobacco to a considerable extent. In the middle of April he noticed that the fingers of both hands were very white and icy cold. This lasted for two weeks and was followed by superficial gangrene, discoloration and blackness of the four fingers of both hands, a little discoloration of the left ear, and a spot on the opposite ear. This con-

dition had lasted for ten days before he came to the hospital. He suffered intolerable pain and got very little sleep. The urine showed slight traces of albumin, a decrease in urea and pronounced amount of indican. The patient had a very high pulse and was given doses of nitroglycerin with strychnine and caffein to improve the circulation. Lead-and-opium dressing was applied and gave relief.

Dr. Pritchard said that this patient was under his care for three or four weeks. At that time the man had, in addition to the symptoms mentioned, extreme edema of the hand, extending beyond the wrist. He had almost the national combination of colors—blue finger-tips, red hand, white arm. He was not relieved by the lead-and-opium applications made in varying strength and by various local means. To him the patient admitted a rather gross alcoholic history and he was of the opinion that this was an etiological factor of some importance, possibly intensified by extremes of heat and cold to which he had been exposed. His sufferings were horrible. Opiates in moderate quantities to modify the intensity of pain were used. He had improved.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held Monday, October 8, 1900.

The President, Robert F. Weir, M.D., in the Chair.

Hydrotherapy in Typhoid Fever.—Dr. S. Baruch read this paper. He stated the only absolutely reliable statistics in medicine are those relating to the Brand method of treatment. Vogel's statistics at the Military Hospital in Munich covered a period of fifty years, and showed a reduction of the mortality from 20 per cent. under other methods to 2.07 per cent. under the Brand treatment. While this plan of treatment has been generally adopted in the hospitals of this country, it has not as yet met with its deserved acceptance in private practice. The success of cold bathing is due to its marked reduction of the lethal complications of the disease. With reference to the cold bath as a means of diagnosis, he said that any patient with a temperature of 103° F. for three days should be first sponged over the trunk and thighs, commencing with water at a temperature of 85° F., gradually reduced to 65° F. He should then be taken to the bathroom and given a bath in water at 90° F., lasting fifteen minutes. Four hours later the bath is to be repeated at a temperature of 85° F.; four hours afterward at a temperature of 80° F., and four hours after that at a temperature of 75° F. If in half an hour after the bath the temperature of the body is reduced two degrees it can be concluded that the case is not one of typhoid; but if in half an hour the reduction does not exceed one degree, the diagnosis of typhoid can be made. A tin bathtub should then be procured and placed by the side of the bed. Having described the manner of giving the baths, he said that if reaction is poor this can be efficiently aided by the addition to the bath of Nauheim salts, in accordance with the suggestion of Dr. Thomson. If for any reason the use of the cold bath is impracticable or inadvisable, various substitutes for this might be resorted to. It should always be borne in mind, however, that the more nearly the method of treatment employed approached the regular Brand treatment, the greater would be the prospect of success. He spoke of ablutions and then of affusions, and said that the latter may sometimes be advantageously combined or alternated with ablutions. Affusions were employed as long ago as 1795 by Curry of Edinburgh, and in the form of what was known as "slush baths" were used with excellent effect in the recent Spanish-American war. Having referred to the sheet bath and towel bath, he read a letter recently received from Dr. Hobart A. Hare of Philadelphia in which the latter described the ice-rub, as practised by him. It has this advantage over the tub bath, namely, that cold and friction can be applied to the great muscles of the back and thighs, which are great generators of heat. The aim of all cold-water methods, he went on to say, is not to depress, but to refresh, and, if properly applied, there will be no shock, no cyanosis, no chattering of teeth. Various procedures should be resorted to according to the varying conditions present. In a case of hypostatic pneumonia complicating typhoid, where there was cardiac adynamia due to sepsis he had used the wet compress with the most happy effect.

In the discussion of the paper Dr. Ransford Van Gieson of Brooklyn said that, after a very extended observation, he could safely say that there is no other method of treatment that in its results at all approaches the typical Brand treatment. Sometimes, however, it is impossible to overcome the prejudices of patients or their friends against the full cold bath, and then we have to resort to substitutes. One method that he has found very efficient is the use of rubber sheeting. This is arranged in the shape of a trough, and affusions made over the patient. He has also used ice-friction with excellent results, and, as it is very difficult to hold a piece of ice in the hand or with a towel, he has devised a simple spring clip, with a wooden handle, for the purpose. The ice should be passed rapidly over the surface.

Dr. Baruch said he does not claim that all patients can be saved by the Brand method, but only that it is, as statistics show, the best treatment that had as yet been found for typhoid; and, moreover, that no patient had ever been killed by the treatment when it was properly given.

Hypospadias.—Dr. Carl Beck read a paper with this title. He gave a brief historical résumé of the subject, and spoke particularly of the achieve-

ments of Dupuytren in remedying the condition. He then described his own special operation, which was first performed in May, 1897. Instead of forming a new urethra, he utilizes the urethra already existing. The *modus operandi* of the procedure is based on the great mobility of the structures of the penis and the expansibility of the urethra. He described in detail the technic of the operation and a number of modifications applicable to various conditions, and stated that the younger the subject the greater the dimensions that can be obtained in the urethra. Dr. Beck presented three patients who had been successfully operated upon—one of them being an infant only five months old.

Dr. John H. Branth referred to so-called hermaphrodism, and mentioned a case he had the opportunity of examining twenty-five years ago which had been pronounced by Virchow and other observers one of real hermaphrodism. This was a mistake, however, as the patient proved to be a male, and Dr. Branth stated his conviction that there was no such thing as a true hermaphrodite.

Dr. Beck then said that several years ago he presented at the Surgical Section of the New York Academy of Medicine a patient who was a true hermaphrodite, the condition being afterward verified by autopsy.

NEW YORK ACADEMY OF MEDICINE.—SECTION ON PEDIATRICS.

Stated Meeting, held Thursday, October 11, 1900.

Thomas S. Southworth, M. D., Chairman.

Muscular Pseudohypertrophy.—Dr. Sara Welt Kakles presented a case of this rare dystrophic disease. The patient is about six years old and the pathological condition was first noted some two years ago, but probably existed even before that and began between the second and third year. In the matter of treatment very little can be done. Something can perhaps be accomplished by prophylaxis. The disease is prone to run in families, and marriages between families in which tendencies to it exist should be discouraged. Children of parents in whose families cases of pseudohypertrophy have occurred should be carefully protected from trauma and from infectious diseases. Sometimes the course of the disease seems to be rendered slower by hydropathic remedies with electricity and massage, care being taken, however, not to irritate excessively the weakened nerves. In discussing the case Dr. Charles Herman said that young children who have suffered severely from rickets may sometimes be observed to raise themselves from the floor by climbing up on themselves, as do these pseudohypertrophic patients. The disease is said to begin at about the sixth year. Some weakness of the limbs has usually been noticed before this, however, and the disease probably begins much earlier in life than is thought.

Fibrinous Pericarditis.—Dr. Bovaird presented the specimens from a case of meningitis with many complications. The first symptom was a pneumonic patch in the left lung. Then a stiff neck was noted and a spasmodic condition in the muscles on the right side. Meningitis was suspected. After this had continued for a day the child died and the autopsy revealed a fibrinous pleurisy with an exudate over an eighth of an inch in thickness covering the pleura. There was a fibrinopurulent pericarditis, but the surprise of the autopsy was a thick exudation of purulent character extending all over the brain and cord. The pathological condition had evidently existed for several days at least, yet the first symptom of meningeal trouble was noticed only twelve hours before death. It is not unusual, however, for extensive nervous lesions to exist in very young children with very slight symptoms. It is a warning not to give too favorable a prognosis in children's ailments.

Symposium on Antitoxin.—Dr. Henry F. Koester, Medical Inspector of the New York Department of Health, read a paper embodying the conclusions formed after six years of experience with the antitoxin treatment of diphtheria. He said that his present attitude toward diphtheria is very different from that of ten years ago. Then diphtheria was a dreaded disease. Now he can be sure if he sees the case during the first forty-eight hours that it will be better in forty-eight hours. His present custom in suspicious throat affections is to give antitoxin and then make the bacteriological test for the disease. Should the test prove that the disease is not diphtheria no harm is done, whereas if the bacteriological examination is positive the disease is throttled at the very beginning

Antitoxin Dosage.—The dosage of antitoxin should be regulated rather by the extent of the disease and the length of time it has existed than by the age of the patient. Dr. Koester considers that 2000 units should be given to mild cases; from 3000 to 4000 if the uvula and tonsils are affected; from 4000 to 5000 if the nares are involved. All laryngeal diphtheritic affections must, of course, be considered as severe cases and must receive the higher doses. If the diphtheritic deposit on the pharynx fails to disappear, then the dose of antitoxin should be repeated, but not otherwise. In all septic conditions from 5000 to 6000 units of antitoxin should be given at once.

Extraoral Diphtheria.—It is often noticed in houses where children are down with diphtheria that other children suffer from nasal discharges or from eye discharges in which, not infrequently, diphtheria bacilli are found. An injection of antitoxin will at once put an end to the discharge and this therapeutic test is the best proof of the real origin of such discharges.

Technic of Injections.—Many people have the habit of making the antitoxin injections into the muscles of the back. This sometimes produces discomfort, however, and there is some slight danger, if the child should move, of the hypoder-

mic needle entering the pleura or injuring some of the internal viscera. If the injection is made into the gluteal muscles these objections do not hold. The child may be easily and firmly held in the requisite position by placing it across the knee with its legs between the doctor's knees. The injections in the gluteal region may be made so deeply as to leave no swelling, whereas in the back swelling remains for some time.

Immunization.—From 150 to 300 antitoxic units are usually given for immunizing purposes, but in tenement-houses Dr. Koester prefers to use from 300 to 500 units because of the insanitary conditions. He has immunized in all some 1800 cases. In 4 cases only did membrane develop in the throats of immunized patients within thirty days after the injection. In one of these true diphtheria developed on the thirtieth day. The membrane in the three other cases proved on bacteriological examination to be due to the streptococcus. Dr. Koester has had complications occur after the administration of antitoxin in but very few cases and then only an urticarial rash that lasted for a day or two.

Accessory Therapeutics—Certain local measures Dr. Koester believes should be employed in some cases. If an offensive odor is noticed dilute hydrogen peroxide should be thrown into the fauces about every hour with a syringe that holds about an ounce of liquid. The solution should be thoroughly neutral. If it is acid it will irritate the lips and is apt to make the inside of the mouth sore with the result that nutrition is interfered with. Where considerable membrane exists in the nose peroxide should be forcibly injected into the nostrils. During nasal injections older children should be instructed to keep their mouths open so that infectious material from the throat may not be forced into the Eustachian tube. In smaller children the mouth should be kept open by a gag if necessary. Internal medication in Dr. Koester's experience is not advisable. Chloride of iron and chlorate of potash disturb the stomach and fulfil no rational indications. The tonic effect of the syrup of the iodide of iron, however, will often be found to do good. Tonic treatment must be the rule. The child should be encouraged to eat as soon as the appetite begins to come back. It should be given anything that it likes—ice cream, for instance, will often tempt the appetite when everything fails. Dr. Koester has had one child practically kept alive for several days on beer. He does not recommend beer for children's dietary, but the incident shows what out-of-the-way material may prove of service. If the child refuses to eat or drink it is better to feed it through the nose by means of a stomach-tube than to resort to rectal feeding. Calomel inhalations have been recommended by many, but they do no good and are prone to salivate those in charge of the little patient. Steam prevents ventilation and the benefit it affords does not make up for the nuisance that it is. After intubation only water should be given for twenty-four hours, after which the greatest care should be exercised in the giving of food until the child becomes accustomed to swallowing it without allowing any of it to get into the lungs. In severe cases the heart will usually need some stimulation. The maintenance of the circulation will prove, too, a prophylactic against the development of bronchopneumonia. The itching of urticaria should be treated in order to avoid the restlessness which it induces. A mild carbolic ointment is the best for this purpose.

Quantity and Grade of Antitoxin.—Dr. William H. Park, Assistant Director of the Research Laboratory of the New York Department of Health, said that the tendency of the present day is to use large doses of antitoxin. In Boston doses which in New York would be considered excessive have been given without any bad effects resulting, although these have been carefully looked for. During the months of August and September alternate cases of diphtheria admitted to the Willard Parker Hospital, irrespective of the severity of individual symptoms, were treated with 1000 and 2000 units of antitoxin each. It must be borne in mind, of course, that antitoxin is not a drug, but a substance which neutralizes the diphtheria toxin. One thousand units is not a small dose. It is sufficient to neutralize the toxin in two liters of bouillon culture of a virulent diphtheria bacillus. It would suffice to protect 100,000 guinea-pigs against a fatal dose of diphtheria toxin. We wish, therefore, to use only the amount of antitoxin that will be sufficient to neutralize the diphtheria toxin present in the system of the patient. Antitoxin is a powerful remedy and its exact dosage would be an important therapeutic advance.

Statistics of Cases.—In all 93 cases admitted to the Willard Parker Hospital suffering from diphtheria died or were discharged during the months of August and September. As was stated, each second case received twice the dose of the preceding one, that is, 2000 units. There was no marked difference in the mortality of the two series of cases. It was found, too, there were no more complications after the larger dose of serum than after the smaller ones. Urticarial rashes were not more frequent and there were no joint or kidney symptoms that could be attributed to the antitoxin. There was some difference in the morbidity of the two series of cases. The symptoms did not clear up so fast in the case in which the smaller doses were given. There was also an impression produced that some of the fatal cases might have been saved if still larger doses of antitoxin had been given. At the Willard Parker Hospital the effects of still larger dosage, 4000 and 6000 and even 8000 units, have been compared. As the result the following conclusions seem to be warranted: In mild cases of diphtheria, seen during the first twelve to eighteen hours of the illness, give from 1000 to 2000 units; in moderately severe cases give from 2000 to 3000 units; in severe cases from 3000 to 5000; all laryngeal cases should be given about 5000 units. If there is no change in the symp-

toms repeat the dose in eighteen hours. Give the first dose at once if diphtheria is suspected. Do not wait for the result of bacteriological investigation. The patient's throat, rather than the temperature or general condition, should be the standard by which the dose of antitoxin is determined.

Quality of Antitoxin.—The serum of any trustworthy manufacturer should be used provided, of course, that it be fresh. With any serum rashes may occur and there seems to be at present no way of avoiding them, although there did seem some hope that the quality of antitoxin in this respect might be improved or that other ingredients in the serum besides the true antitoxin were responsible for the untoward effects and that they might be eliminated. A globulin has been extracted from diphtheria serum which contains all the antitoxic property, but which gives no more assurance of not causing rashes than does the whole serum.

Antitoxin in Boston.—Dr. John McCullum, Resident Physician at the Boston City Hospital, discussed the present state of opinion with regard to antitoxin according to experience in Boston. In 1890 diphtheria was the seventh on the list of fatal diseases in Boston's death-rate. In 1899 it was the sixteenth on the list. There has been since the introduction of antitoxin a marked and continuous diminution of the death-rate from diphtheria in the city. This is more noticeable than in any of the other large cities—Glasgow, Liverpool, Paris, Berlin, or London. Whereas the death-rate from diphtheria was over 35 per cent in 1881 it was only 10 per cent. in 1899. The death-rate of intubation cases in the Boston City Hospital has been reduced from 87 per cent. to 32 per cent. In the Willard Parker Hospital in New York the average mortality of intubation cases has been reduced from 85 to 52 per cent.

Large Doses of Antitoxin.—Much has been said about the dangers involved in the use of antitoxin. To some minds this is the main objection to its use. In a series of cases in the Boston City Hospital very large doses of antitoxin have been used, not only without producing any bad effect, but in reality saving patients from what seemed an inevitable fatal termination. Dr. McCullom then reported a series of cases in which from 30,000 to 60,000 antitoxin units had been used in the treatment of diphtheria. In one the child came in on the fifth day practically moribund; 4000 units were given at once and this dose was repeated every three or four hours for several days until 60,000 units had been injected. The patient recovered and suffered from no unusual complications. In a second case the patient was in the sixth day of the disease, a delicate child of only eight years, with an abundant mucopurulent discharge from the nose and a very disagreeable odor. Some edema of the face was already noticeable. In four days 40,000 units of diphtheria antitoxin were administered and the child recovered. A mild urticaria resulted, but the albumin that was in the urine when the child entered the hospital disappeared during the course of the injections of antitoxin. In this case some palatal palsy was noticed and an irregular heart action, but after a little time these disappeared. In a third case a pair of hypertrophic tonsils were completely covered by diphtheritic membrane which had also invaded the nostrils in the back of the pharynx. The treatment was not begun until the fifth day of the disease and 52,000 antitoxic units were given during the five days of active treatment. In a case brought into the hospital on the fourth day of illness and in which ordinary doses of antitoxin had had no effect, 35,000 antitoxic units were given in large doses at short intervals and improvement soon began, followed by ultimate recovery. In a fulminant case of diphtheria, seen for the first time on the third day, in which there was intense prostration and everything pointed to a rapidly fatal issue, 50,000 units of antitoxin seemed to bring the patient back from the verge of the grave.

Technic of Large Dosage.—No rule can be given as to the amount of antitoxin that should be given in severe cases of diphtheria. Beginning with from 300 to 500 units, the dose should be repeated every four to six hours until the diphtheritic membrane begins to shrivel, the odor of the discharge to modify, and a favorable reaction in the general condition sets in. No bad effects were noticed from these large doses, although the condition of the patient was carefully watched in order to obtain assurance on this point. Dr. McCullom has never seen a death from diphtheria where antitoxin was administered during the first twenty-four hours of the disease. If 4000 units of antitoxin are administered as soon as a suspected case is seen, the diphtheria will not last long and there will be no heart complications. It has been objected that antitoxin produced albuminuria. In over 600 cases the urine of diphtheritic patients was carefully examined for albumin. In no case was there an increase of the albuminuria so frequently present during diphtheria and in no instance did a suppression of urine occur after the administration of antitoxin. Where the antitoxin treatment was begun early there was always less albuminuria at a given stage of the diphtheria than would be regularly found in an untreated case.

Hospital Diphtheria.—One hundred and four cases of diphtheria have occurred in the Boston City Hospital in members of the medical or nursing staff since the introduction of the antitoxin treatment. In every instance the cases have been treated at once with antitoxin; there has not been a single death and recovery has been rapid.

New Bacterial Laboratory.—The contracts for the new laboratory of the city of New York for the study of the bacteria of plague and other infectious diseases have just been let.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, NOVEMBER 10, 1900. NO. 19.

ORIGINAL ARTICLES.

SOME OBSERVATIONS ON ANESTHESIA BY INTRASPINAL INJECTIONS OF COCAINE.[1]

BY S. ORMOND GOLDAN, M.D.,

OF NEW YORK.

HAVING used the lumbar puncture and injection in over twenty cases, covering a variety of operations in general surgery, gynecology, and obstetrics, it is rather to be expected that, as an anesthetist, I would make comparisons of the new method with our general anesthetics, nitrous oxide, ether and chloroform.

That intraspinal cocainization would be superior to general anesthetics as administered in many cases, there is no doubt. That it is superior either in safety or advantages to our three general anesthetics properly selected and skilfully administered, I for one do not believe. My opinion is not based upon purely theoretical grounds, but upon a considerable practical experience in the administration of general anesthetics and an experience in the intraspinal method of anesthesia which, while less extensive than that of others, perhaps, is none the less thorough in the observations recorded.

While my results were at variance with others recorded in this vicinity, it has been a matter of satisfaction to find they were practically the same as those of the operators who first used the method for surgical purposes. I refer to Bier and Tuffier and, recently, those who at first questioned my technic.

It is my purpose to call attention to some salient features usually passed over by other investigators. First, it may be of interest to see the armamentarium complete. This consists of needles, aseptic solid piston syringe, one 120 m. graduate, small medicine glass for cocaine solution, test-tubes containing sterile cotton, forceps; sterile water in a tube covered by a sterile finger cot, effectually avoiding the loss of the fluid, at the same time keeping it uncontaminated; a small bottle of collodion, adhesive strips, a small piece of Arkansas oil-stone, alcohol lamp, powders of cocaine hydrochlorate, grs. 1¼ each, first wrapped in paper, then covered with foil and carried in a wide-mouth, glass-stoppered bottle large enough to hold about six. These are all tightly packed in a copper sterilizer, 8 x 6 x 2. I advise that they never be used for any other purpose.[2]

The needles should be neither too large nor too small in caliber. The attenuated needles and stylets devised by me are made of gold drawn, rendering them for this purpose second only to steel with none of the latter's disadvantages. The measurements are 8 and 10 centimeters respectively in length. External diameter of larger part, .9 millimeter. Internal diameter of larger part, .8 millimeter. External diameter of attenuation, .8 millimeter. Internal diameter of attenuation, .4 millimeter.

The attenuation, the essential part of the needle, is three centimeters from the point, which has a short bevel. It will be noticed that the measurements of these needles are smaller than those recommended by Tuffier. In no instance have I failed to obtain the cerebrospinal fluid nor have the needles up to the present ever become stopped up—it can readily be seen that were this to happen the stylets would very quickly and effectually clear them. Devices for causing a vacuum in the needles as they pass through the tissues are rather a disadvantage as they tend to draw foreign materials into them which would not ordinarily occur. The trocar and screw-nut of Corning's are quite unnecessary. The smaller the opening in the integument, everything else being equal, the better.

In most instances the line uniting the iliac crests in the mid-point of the back skirts the lower border of the spinous process of the fourth lumbar vertebra; at times it passes through the middle of it. The practical point to remember, whether it passes through or just below it, is that it is the fourth vertebra and the site of puncture is between this and the fifth, not more than 1 cm. external to it on the right or left side. If the needle is directly in the space between the contiguous vertebræ it need only be pushed in from without inward. It is only when it is introduced too low that it impinges upon the lamina of the vertebra below; it must then be depressed and also pushed from below upward to enter the spinal canal. The punctures have been made by me with such extreme ease that I can tell the instant it enters the interlaminar ligament and membranes of the cord and the moment the fluid will appear. The needle should be thrust through the skin quickly; then, giving the patient time to recover from the slight shock, it is gradually pushed inward, bearing in mind, the direction until the subarachnoid fluid appears. This should not be allowed to drip away; but the syringe filled with the required quantity of cocaine solution is adjusted to the needle and the cocaine slowly injected, about one minute being consumed in doing it. The needle is not immediately withdrawn, but is al-

[1] Read before the Section on Obstetrics and Gynecology of the New York Academy of Medicine, October 25, 1900.

[2] For a complete description of the technic see the author's paper read before the New York State Medical Association, October 18, 1900, and published in the *Philadelphia Medical Journal*, November 3, 1900.

lowed to remain *in situ* about two minutes. It should be distinctly remembered that my observations are based upon the injection of 20 m. of a two-per-cent. solution of cocaine, the injection being sometimes repeated, but never more than once.

Anesthesia appears in from two to twenty minutes and is evinced usually by a paresthesia in the lower extremities variously described by different patients. Some are not cognizant of this paresthesia until the effort is made to rise from the chair; they then imagine they cannot move. Motion is not impaired, however, for when they are told to bend the legs, etc., in most instances they can readily do so. Anesthesia in my experience frequently extends to the axilla, occasionally to the clavicle, at other times to the lower ribs or umbilicus, the middle of the thighs or only to the ankles; it is usually symmetrical, occasionally higher on one side than on the other; in one case it was present upon one side only and this from the buttock down along the posterior aspect of the thigh and leg to the ankle and across the instep and the whole sole of the foot.

In some patients well-developed paresthesia was noted in the upper extremities in one of these. The patient was in the Trendelenburg position. Sensation to pin-prick was present, however.

The duration of anesthesia varies in different patients, the longest period being three hours. I doubt, however, if it was sufficiently complete to be available for surgical purposes; in most instances no doubt it would be for operations on the lower extremities; in abdominal operations patients who still have anesthesia in the lower extremities have decided sensations during manipulations toward the end of the procedure. An anesthesia for an abdominal case lasting one and one-half hours in my estimation would be long. Anesthesia often passes off much sooner, in one case it lasted but forty minutes.

Muscular relaxation is very complete; the sphincters often lose their tonicity, in one case the rectal contents were forcibly expelled during vomiting. Voluntary contraction of muscles is present; expulsive effort is not impaired. The respiration in all patients is increased, frequently doubled, the normal rate usually varying between 24 and 30, at times shallow, at other times full; one patient had evident air hunger, but this quickly passed off. The pulse immediately after injection is always increased in frequency, usually about 120—at times higher; sometimes it is small and often within a half hour falls as low as 60 and becomes full; sometimes it is irregular; it then increases in frequency to something above the normal rate. The decrease in the pulse is not followed by a like decrease in the respiration. Less than half the patients had nausea and vomiting. When it did occur it came on at times soon after the injection and sometimes half an hour after. In one case nausea was very intense. It usually quickly ceased, but occasionally occurred the following day. Many patients exhibited marked pallor of the face with a slight cyanosed condition about the lips and tips of the fingers; later on the face became suffused, showing a decided contrast to the previous condition. The pupils in most instances were normal, at times slightly dilated but never markedly so; the rather darkened condition of the room could account for the slight dilation. Occasionally the pupil was contracted, particularly so in one case after a hypodermic injection of morphine. Perspiration more or less profuse occurred in all but two cases. I attribute this to paralysis of the sympathetic similar to that caused by general anesthetics. The temperature sometimes rose as high as 103° F. There was some rise of temperature in more than half the cases. In one patient it reached 103.4° F., but as there was a pus pocket associated with the case the surgeon attributed the temperature to that. After this was opened the temperature gradually approached the normal. Headache in the occipital or frontal or temporal regions occurred in half the patients; in four it was very intense; in the others only moderately so. In most of the patients it passed off in twenty-four hours, leaving a dull feeling about the forehead. Some of the patients had slight rigors and a condition of restlessness the following day, with dull aching in the bones, particularly of the lower extremities. Two of the patients had muscular rigidity of the muscles of the back and of the back of the neck; in one patient this persisted for a week.

Some of the patients were entirely free from all subjective symptoms. Anesthesia failed entirely in three cases, in two of which more than half a grain of cocaine was injected. In others anesthesia was partial; in still others a second injection produced satisfactory anesthesia. Marked toxic symptoms developed in one patient, an obstetric case. The respiration was gasping, shallow, and 60 to the minute; pulse 140, small and irregular; profuse perspiration; muscular tremors; face absolutely colorless, pupils contracted. This patient had very intense headache for two days following the injection.

Deductions based upon my own experience and also the reports of other investigators which do not materially differ from mine can be summed up as follows:

1. Cocaine introduced into the subarachnoid space acts in the same way as it does when injected into the general circulation, being, possibly, less toxic.

2. There is no definite quantity which will answer in all cases. Some are easily influenced by small doses, whereas others require large amounts to produce the desired effect.

3. Temperament, type of patient, and condition of health do not seem to influence the action of the drug. Large, healthy individuals are often affected by small doses, whereas the sickly, emaciated types often require second injections to produce anesthesia.

4. There is no method of determining how

any particular dose will act in a particular case.

5. Large doses should never be used until the individual susceptibility is determined.

It is singular that when a first injection produces no anesthetic effect it also produces slight physiological symptoms. A second injection may then be made with safety. When anesthesia is but partial a second injection may be made, this to be less, however, than the first.

This is the only practical and safe plan to be followed in all cases. Differing in no way from toxic drugs introduced into the general circulation, it has been said that a large dose, say of morphine, often produces the desired effect when a small one does not. This is quite true. I do not believe any one would introduce what might be a toxic dose of morphine without first ascertaining the patient's individual susceptibility. Cocaine differs in no way from morphine in this respect. In a case reported by Boldt[1] some years ago the injection of a few drops of a four-per-cent. solution produced very toxic symptoms which almost caused death. Cocaine was just beginning to receive attention as a local anesthetic. A patient with supraorbital neuralgia had injected 15 m. of a four-per-cent. solution of cocaine. There was first observed redness of the face, then vertigo, increased pulse with diminution of volume, frequent short respirations and distress about the region of the heart; after two or three minutes the patient fell unconscious to the floor. Respiration ceasing entirely, artificial respiration was employed and the patient restored after fifteen or twenty minutes. Respiration became spontaneous to the extent of 5 or 6 to the minute, deep and sighing; pulse weak; pupils dilated, without reaction to light; conjunctivæ sensitive however. Previous to regaining consciousness there was observed spasmodic contraction of the upper extremities. Speech was incoherent and after one hour the patient walked with unsteady gait. The neuralgia was absent for three days; then a second injection was made at the urgent request of the patient, 10 m. of a four-per-cent. solution were injected and the symptoms occurred in exactly the same order, only not lasting so long. A third injection of 5 or 6 drops produced vertigo, dyspnea, oppressive feeling about the heart; the symptoms disappeared in a few minutes. Boldt's experimental researches upon animals differ more in degree of intensity of symptoms than kind; the latter were very similar to those which developed in the obstetric patient before mentioned.

Whether intraspinal cocainization will prove to be more valuable in obstetrics than in general surgery, time alone can tell. The marked toxic symptoms and the disagreeable after-effects may be found to more than offset any advantages which the method may possess. It is probably not generally known that cocaine was used locally in obstetrical cases by Dr. Polk of this city fourteen years ago. An interesting account of his experience with it appears in Knapp's monograph on "Cocaine," published by G. P. Putnam's Sons. The injection of 4 m. of a four-per-cent. solution of cocaine into the anterior and posterior lips of the cervix produced anesthesia for one hour during the first stage of labor, during which time the patient complained only of discomfort over the symphysis and of some dull pain over the sacrum; the cervix could be stretched freely without causing pain. During the second stage injections were made in the vaginal walls along the course of the distribution of the pudic nerves, and the results were so far satisfactory that the child's head passed out of the vagina with so little discomfort that the patient uttered no complaint. Dr. Polk told me the method fell into disuse because it offered no advantages over chloroform.

It has been said that intraspinal cocainization has produced no mortalities. I believe Tuffier reports at least one case in which the patient died of asphyxia which can be attributed to cocaine. It is no more than just, however, to state that the safest anesthetic introduced would eventually have deaths attributed to it, but fatalities occurring during narcosis are not necessarily due to the anesthetic.

How does the method compare with our general anesthesics? Retention of consciousness is said to be one of the advantages. Were this question canvassed among patients generally the vast majority would prefer to know nothing while being operated upon. It is said to be advantageous in cardiac disease. It has so frequently been my office to administer anesthetics to patients suffering from organic cardiac disease with such satisfactory results that I can see no advantage in this method over ether or chloroform properly selected and administered. In fact, I would consider cocaine less safe because of its marked circulatory involvement. It is not so much the organic lesion as the character of the heart's action which indicates whether a patient is apt to behave well under general anesthesia.

Absence of pneumonia and nephritis is another advantage mentioned. Were every patient who takes a general anesthetic to develop these complications there would be no question but that intraspinal cocainization would be the method *par excellence*. As a matter of fact, pulmonary and renal complications are rare following general anesthesia, particularly so when properly administered.

In certain forms of renal disease intraspinal anesthesia would undoubtedly be safer than ether or chloroform. Take, for instance, a patient with a well-developed nephritis, a secondary bronchitis and irregular heart-action: while ether properly administered would no doubt stimulate the heart, it would be obviously unsafe for the kidneys and lungs: chloroform would be selected as the safest anesthetic: in spite of every precaution renal suppression occurs. Spinal

[1] *New York Medical Press*, 1885–6, p. 105.

anesthesia would be the safest method in such a patient and I would have no hesitancy, providing nitrous oxide and oxygen were not applicable, in advising its use in preference to ether or chloroform, for I have seen just such suppression occur when chloroform as well as ether was being employed as a general anesthetic. Fortunately, however, such cases are extremely rare, but the possibilities should always be borne in mind by the surgeon and anesthetist.

When the patient has an ungovernable fear of general anesthetics and refuses to have them administered, the status of intraspinal anesthesia may be stated to him and it may be used providing he prefers it and fully comprehends the dangers of the method.

In spite of every precaution in technic failure to produce anesthesia does occur. This is most frequently and I think improperly attributed to the boiled solution. It is questionable whether cocaine freshly prepared and boiled one minute is rendered inert. A decided disadvantage is the uncertainty as to the time anesthesia will last. No more deplorable condition is conceivable than to have the anesthesia pass off during an important part of an abdominal operation. The method should not be used in minor cases where the puncture and injection are in magnitude altogether out of proportion to the operation.

To sum up: To me, with the experience gained to date—I shall, however, have no hesitancy in altering my views should further observation warrant it—anesthesia by intraspinal cocainization will have a place in surgery not as the method for general use, but when for various reasons general anesthetics should or cannot be administered. While this does occasionally occur, it is exceedingly rare. There are few patients requiring operations who cannot take one or the other of our three general anesthetics. I see no reason to change what is in my estimation the order of safety of anesthetics except to add to the end of the list intraspinal cocainization. This may be stated as:

1. Nitrous oxide and oxygen.
2. Nitrous oxide and air.
3. Ether preceded by nitrous oxide.
4. Ether alone.
5. Chloroform preceded by nitrous oxide and ether.
6. Chloroform preceded by ether.
7. Chloroform alone.
8. Intraspinal cocainization.

With reference to 5, 6 and 7 it is my belief that 75 per cent. of the early fatalities from chloroform could be prevented by the preliminary administration of gas and ether or ether alone.

When intraspinal cocainization has been used with a mortality comparable with nitrous oxide and ether, then and not until then will we be in a position to definitely assert that it can be safer than that most generally useful and safe combination of anesthetics.

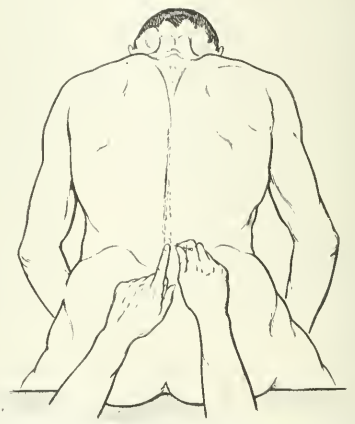
226 West 45th Street.

FURTHER EXPERIENCE WITH SUBARACHNOIDEAN INJECTIONS OF COCAINE FOR ANALGESIA IN ALL OPERATIONS BELOW THE DIAPHRAGM.

By JOHN B. MURPHY, M.D.,
OF CHICAGO;
PROFESSOR OF SURGERY AND CLINICAL SURGERY IN THE NORTHWESTERN UNIVERSITY MEDICAL SCHOOL; SURGEON TO THE MERCY HOSPITAL, ETC.

THE history of subarachnoid cocaine anesthesia is familiar to readers, and it is unnecessary to consider it in this article. We wish to mention the practical results of this procedure from a clinical standpoint, after considering its technic. Its administration in the great majority of cases is easy. The patient is placed in a sitting posture, with the body bent sharply forward so as to separate the spinal laminæ as much as possible. The skin, having been sterilized in the usual way, a needle, two and a half inches in length, with a short bevel, is inserted between the

FIG. 1.

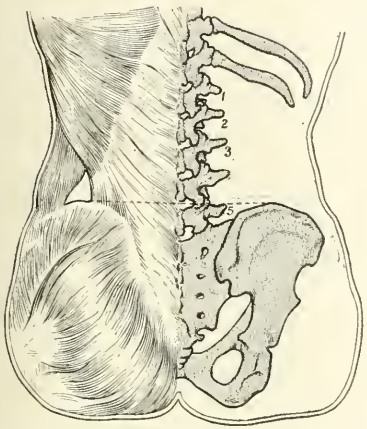


The patient sits upon the edge of the table; the operator having previously localized the iliac crests, with the left index finger he locates the spinous process corresponding to the bi-iliac transverse line. The needle is inserted with the right hand 1 cm. in front of this apophysis. (Cut after Tuffier.)

fourth and fifth lumbar vertebræ. The thumb should be placed upon the spinous process of the fourth, so that its tip passes a little below and to the left of the process. The needle is then inserted directly forward, not tilted upward, until the resistance of the interlaminal membrane is encountered. When the needle is pushed slowly through this the cerebrospinal fluid escapes, sometimes in drops and sometimes in a stream. The syringe should now be connected, and fifteen minims of a one-and-one-half or two-per-cent. cocaine solution slowly injected, a process requiring from thirty to forty seconds. The needle is then withdrawn, and the opening closed with collodion. The patient is placed in the recumbent position and preparations made for operation. The analgesia is complete in from six to eleven minutes in all cases.

The dangers of failure in technic are: (1) The cocaine solution may not be fresh, and therefore may have lost its analgesic properties. It must be borne in mind also that cocaine undergoes

Fig. 2.



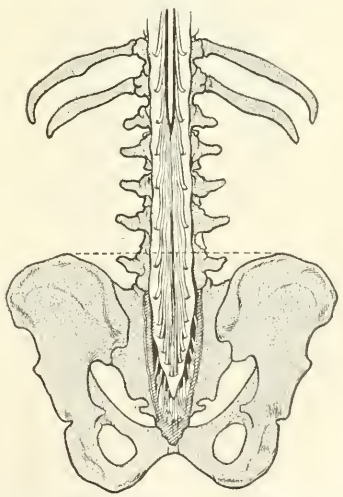
The broken line shows the vertebra corresponding in position to a horizontal line extending from the uppermost point of one iliac crest to that of the other posteriorly. (Cut after Tuffier.)

decomposition when boiled. (2) The needle may escape from beneath the dura, or be forced through the dura in making the connection of the barrel with the needle. In that event the fluid would escape in front of or behind the dura, and no analgesic effect would follow. When the needle is being inserted, if the interspace is not penetrated in the first effort, it should be partially withdrawn and its direction changed a number of times, as it is likely to become filled with blood, which coagulates and does not allow the cerebrospinal fluid to escape even though the tip be within the canal. In such instances the needle should be removed and washed out with sterile water. In my recent cases I have filled the needle with cocaine solution before inserting it, water answering the purpose just as well, and placed my finger over the end of the needle, so that no blood was admitted into the needle until I felt that I had penetrated the dense membrane between the lamellæ. I believe I have saved myself the annoyance of changing the needle a number of times by following this plan. A fairly strong needle should be used, as in muscular patients its direction is changed very much by the spasm of the muscles when the needle is inserted. I always tell the patient that a needle puncture is to be made; that he will not be unconscious; that he will know everything that is going on, and still he will have no pain.

I wish to call particular attention to Case XXIV., as it emphasizes the importance of a fresh solution. There was also one case in which I was unable to find the interspace between the laminæ, as the patient could not be placed in a sitting position, and his back was somewhat deformed on account of ankylosis.

The manifestations, after the injection, as given by the patient, occur in the following order and at about the average time herewith given: A sensation of numbness in the feet and legs comes on about four minutes after the injection. This rapidly extends up to the trunk and as high as the costal arch. Five minutes after the injection the patient complains of thirst, a tingling in the tongue, a sensation of anxiety in the precordial region, and a sense of heat. From eight to twelve minutes after the injection many of the patients are nauseated; some of them vomit. Six or seven minutes after the injection there is usually a slight increase in the pulse. In some cases it is very pronounced from the moment of the injection, and even preceding it, due to the nervous condition of the patient. In all of the cases cited, except Case XXIV., the analgesia was perfect, and all have progressed to uninterrupted recovery without the least complication. After the patients were removed from the operating-room there was no nausea nor emesis in any of the cases, and it was gratifying to notice the excellent condition of the patients on the evening of the operation. Even the patients upon whom laparotomy was performed were much better than those in whom a general anesthetic had been used.

Fig. 3.



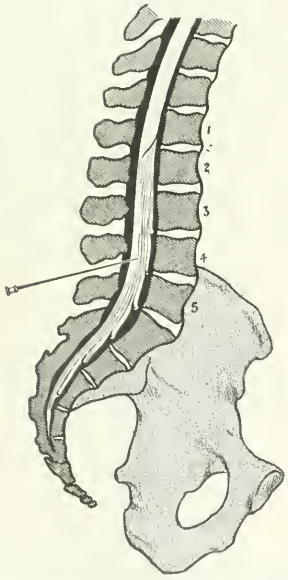
The broken line shows the distance existing between the needle and the spinal cord when the arachnoidean cul-de-sac is penetrated. The spinal cord terminates at the lower border of the body of the first lumbar vertebra. (Cut after Tuffier.)

As the anesthesia is probably due to a local effect upon the posterior nerve-roots and not to absorption, the solution being diluted immediately with the cerebrospinal fluid, I have very much

less apprehension than I had when it was first suggested or when I first saw it used. There has not been a single case of depression of the pulse to the extent which I observed in Tuffier's clinic. Whether this is due to the cocaine or to a difference in the patients, I do not know; but the clinical fact remains that for minor operations, such as operations upon the foot, leg, knee, thigh, and hip, I believe that ten minims of a two-per-cent. solution will be sufficient.

The indications for cocaine cannot be given at the present time from a clinical standpoint. However, I would say that for the operations of strangulated hernia, intestinal obstruction, crushing injuries of the lower extremities, compound fractures, dislocations, operations on the

Fig. 4.



The needle can be seen in the arachnoid space; the nerves being laterally situated are not in danger of injury. (Cut after Tuffier.)

perineum, vaginal hysterectomy, and in intra-abdominal operations when the respiratory tract or the kidneys are at all impaired, cocaine should be the anesthetic of election, as far as we understand it at the present time.

The cocaine may be secured from the manufacturers in solution in vacuum-glass ampullæ, in which it will keep perfectly for two months, or in dry anhydrous crystals in glass ampullæ, marked, containing fifteen minims and thirty minims in amount, to which sterile water may be added at the time of administration. This insures the efficacy of the cocaine and the sterility of the medium.

The syringe should have a slide and not a screw connection, as in twisting the barrel one is likely to dislodge the tip of the needle from beneath the dura.

We do not use this method of anesthesia in every case, either in clinics or in private practice, but each week its range of usefulness is increasing as confidence and security are assured by the results.

Since my return from the International Medical Congress, August 19th, I have used this method of anesthesia in twenty-five cases, with the following results:

Case I.—Miss B., Cook County Hospital, aged twenty-two years; left pyosalpinx, with history of rupture into the intestines. Injection of 15 minims of a two-per-cent. solution of hydrochlorate of cocaine in the subarachnoid space in the lumbar region on a level with the iliac crests. The needle was easily inserted, the cerebrospinal fluid escaped, and about forty seconds were consumed in injecting the fluid after the syringe was connected. The opening, when the needle was withdrawn, was sealed with collodion. The operation was begun eight minutes after the injection. A medium incision was made; the adhesions were very extensive and firm. It was difficult to separate the tube from the bowel. The wall of the latter was enormously thickened, and I feared that a sinus was present. Careful examination, however, did not reveal one. The tube was removed, the pus sponged out, and the omentum drawn over the intestine and pressed down into the pelvis, as the sigmoid was fixed and could not be turned down to protect the abraded surface. The operation was completed by closing the abdomen with figure-of-eight sutures. No drain. The patient was conscious of the fact that she was being handled, but there was not the slightest pain. She was nauseated and vomited six times after the operation was begun, retarding the work a couple of minutes. The pulse at no time exceeded 75 and ranged from that to 60. She did not vomit after the operation. Her temperature that evening reached 102° F.; since then it has been normal and no unpleasant symptom has occurred.

Case II.—Male, aged fifty years, Cook County Hospital. Varicose veins of the leg; Schede operation. Thirteen minims of cocaine. A two-per-cent. solution was used for injection. Anesthesia complete in seven minutes. Some nausea and vomiting during the operation. Anelgesia perfect. The pulse was not accelerated and was strong at all times.

Case III.—Male, aged forty-six years, Cook County Hospital. Sensitive ulcerated stump following amputation for diabetic gangrene. In this case 15 minims of eucaine solution were injected. A little difficulty was experienced in getting the needle between the laminæ. Some nausea and vomiting occurred as with cocaine. It was twelve minutes before the analgesia was complete, and there was some return of sensation ten minutes after the operation was begun. On the whole, it was not as satisfactory as cocaine.

Case IV.—Female, Cook County Hospital;

small tumor of left ovary in a very neurotic patient. Injection of 11 minims of a two-per-cent. solution of cocaine. Nine minutes after the injection the analgesia in the abdominal wall was complete. An incision was made, the ovary and tumor removed in the usual way; abdomen was closed with a figure-of-eight suture. Eighteen minutes after the injection there was one effort at vomiting. The patient said she had a sense of nausea. The insertion of the needle did not give the slightest pain. Her extremities from the toes to the hip were tested with needles. The sense of touch was present, but no pain was produced by the prick. There was no vomiting after the operation. The patient's pulse was 120 before the operation was begun, and 90 when it was completed. Time, twenty-one minutes from the injection to the completion of the operation.

Case V.—G. B., aged eight years, Alexian Brothers' Hospital, September 11th, appendectomy. Intermediate operation; 15 minims of a two-per-cent. solution of cocaine injected. Complete analgesia in nine minutes. Transrectus incision; appendix postcecal; separated from caput coli by pathologic amputation; removed; closed without drain. Pulse before operation, 150; when abdomen was opened, 140; remaining so during the operation of ten minutes. One effort at vomiting twelve minutes after the injection. No vomiting after operation. Temperature same evening, 99° F.

Case VI.—I. S., aged fifty-one years, Alexian Brothers' Hospital, September 11th. Arthrectomy left knee-joint; traumatic synovitis; 15 minims of a one-and-one-half-per-cent. cocaine solution injected; analgesia in eleven minutes. Nauseated; vomited fourteen minutes after injection; pulse 140 all the time; very neurotic patient. Temperature same evening, 99.6° F. No unpleasant after-effects.

Case VII.—Male, Alexian Brothers' Hospital, September 11th. Suppurative epididymitis; curettement. Injection of 12 minims one-and-one-half-per-cent. cocaine solution; analgesia in seven minutes; nausea; vomited once thirteen minutes after injection; pulse rapid all of the time, before, during and after the operation. Temperature, 100.6° F. the evening after operation. No unpleasant symptoms.

Case VIII.—O. H., aged fifty-eight years, Alexian Brothers' Hospital, September 11th. Schede operation. Varicose ulcer of leg. Injection 15 minims of a one-and-one-half-per-cent. cocaine solution. Analgesia of lower extremities in seven minutes. Nausea and slight vomiting. Pulse never above 90. Patient phlegmatic, had no apprehension of pain, discomfort or danger from the operation, contrasting markedly with the previous cases. Temperature, 99.4° F. on evening after operation. It will be noted that in all cases operated on September 11th the evening temperature exacerbation was absent.

Case IX.—H. P., aged thirty-five years, Alexian Brothers' Hospital, September 12th. Strangulated femoral hernia of fifty-four hours' duration. Injection of 15 minims one-and-one-half-per-cent. solution. Analgesia in eight minutes. Usual incision, intestine liberated, gloss was present, circulation slowly returned, resection unnecessary, sac excised and femoral canal closed with kangaroo tendon. Patient vomited before injection and frequently during operation. The vomitus was that characteristic of obstruction. Pulse was 130 before injection, reached 144 during operation, was 120 at completion of operation and fairly strong all of the time. Duration of operation, twenty-two minutes. The patient had no pain or inconvenience at any time during the operation. His bowels moved freely on the table. He said he felt better than at any time since the onset of his illness.

I believe cocaine has very decided advantages in cases of intestinal obstruction; *first*, the patient is quickly prepared for operation; *second*, the danger of inhalation-pneumonia is *nil*, a matter of grave importance; *third*, the prolonged depression so general in this operation from general anesthesia is avoided.

The following cases in my service were by Drs. Lee, Oswald, and Neff:

Case X.—Patient sixty-two years old; suprapubic cystotomy. Fifteen minims of a one-and-one-half-per-cent. cocaine solution; patient did not vomit and the introduction of the sound did not give pain.

Case XI.—Patient fifty-six years of age; papilloma of rectum; 15 minims of a one-and-one-half-per-cent. cocaine solution; sphincter ani dilated; perfect analgesia; no vomiting.

Case XII.—Patient aged forty-two years; varicose veins of leg; Schede; 15 minims two-per-cent. cocaine solution; nausea.

Case XIII.—Patient's age not given; inguinal hernia, radical cure; 15 minims one-and-one-half-per-cent. solution; no vomiting; no pain.

Case XIV.—Aged thirty-four years; inguinal and umbilical hernia; 20 minims of a one-and-one-half-per-cent. solution; time for both operations, 45 minutes; nausea; no vomiting.

Case XV.—Male, aged twenty-six years; cystoscopy of bladder; 15 minims of a one-and-one-half-per-cent. cocaine solution; some nausea; no vomiting; time of operation, 35 minutes. The prostatic portion of the urethra gave an unpleasant sensation, though no pain.

Case XVI.—Male; carcinoma of penis; amputation and removal of inguinal glands, both sides; perfect analgesia; some nausea and efforts at vomiting.

Case XVII.—Extensive burn of the thigh; terminal growths; 40 square inches; 15 minims of a two-per-cent. solution; complete analgesia in nine minutes; some nausea; no vomiting.

Case XVIII.—Female, aged fifty-nine years; intra-uterine polypus; dilatation, removal of polypus, curettement; analgesia in seven minutes; pulse 74 at the highest; no nausea; no vomiting.

Case XIX.—Female; retroversion; polypus; small cyst of ovary; 15 minims of a two-per-

cent. solution; analgesia in eight minutes; laparotomy, removal of cyst of ovary, ventral fixation; considerable vomiting due to the fact that a four-per-cent. solution was imperfectly mixed with sterile water to make it of two-per-cent. strength; time of operation 15 minutes; not the slightest pain at any time.

Case XX.—Mrs. X, aged thirty-four years; large uterine myofibroma. Abdominal myomectomy; 15 minims of a two-per-cent. cocaine solution. In nine minutes analgesia was perfect; median incision. Enucleation of fibroid from uterine wall; double row of silver catgut sutures of uterus; closure of abdominal wall with silkwormgut. No vomiting; analgesia perfect; highest pulse 94. Patient said, "It is just play compared with taking chloroform."

Case XXI.—Male; ankylosis of hip; ununited fracture of femur. It was impossible to put patient in the sitting position and I was unable to insert the needle with the patient on his side. The attempt was abandoned.

Case XXII.—Male, aged thirty-seven years; hemorrhoids; 15 minims of a two-per-cent. solution. In seven minutes the analgesia was complete. The sphincter was stretched without the slightest manifestation of pain or reflex. Tumors removed with cautery and without pain. No nausea and no vomiting.

Case XXIII.—Male, aged twenty-four years, Mercy Hospital; large varicocele; phlebectomy; 12 minims of a two-per-cent. solution (two months old, but in a vacuum-glass ampulla); analgesia was complete in seven minutes; more nausea than usual; no vomiting; complained of sense of heat in chest; pulse 92 at highest; somewhat diminished in force and volume. I saw him an hour after operation and he said he never felt better in his life. No headache or other unpleasant symptoms followed.

Case XXIV.—Mrs. X., aged twenty-six years; Cook County Hospital; acute appendicitis; abscess rectocecal; small appendix removed. Injection of 15 minims of a two-per-cent. solution of cocaine; after ten minutes not the slightest analgesia; no nausea or sense of numbness; no anxiety. Investigation showed that the interne had used an old solution of cocaine which had decomposed from standing. The two bottles were just alike and the mistake was pardonable. I did not dare to use another injection on the same patient, but used the fresh solution immediately on the next case with positive results.

Case XXV.—Mrs. F., aged fifty-two years; Cook County Hospital; tubercular tendovaginitis, dorsal tendons left foot; extensive dissection of the tendon sheaths; injection of 13 minims of two-per-cent. solution of cocaine, fresh; complete analgesia; no nausea and no vomiting; no cardiac pneumonia; patient felt perfectly well after removal to room. This is a beautiful contrast to the previous case, showing the importance of fresh cocaine solution, or one, at least, that has been free from bacterial action.

THE EXAMINATION OF STOMACH-CONTENTS.

By W. A. BASTEDO, PH.G., M.D.,
OF NEW YORK.

NEW laboratory methods when first propounded are apt to repel the general practitioner, because the practical application of them is difficult and the value of their findings not yet established. He does not see how he can use them in his own practice, although he may recognize their value in the hands of the specialist. Yet as time goes on the methods become simplified, a few tubes and solutions replace the early complicated and extensive apparatus, and the results become more definite and of more real diagnostic significance. Then only can the busy practitioner without laboratory facilities begin to use such methods for the benefit of his patients. It is thus that the examination of stomach-contents, which until recently has been carried on only by stomach specialists and clinical chemists, has become an easy undertaking. It is true that among the many processes outlined in works on the stomach no stress is laid upon the value of the simpler methods which can be put into daily practical use, and the reader is made to feel that he must not only be possessed of excellent chemical technic and a compound microscope, but must also expend much time and labor if his examination is to be of any value. That this impression is a mistaken one and that thanks to the realization of its diagnostic significance in internal medicine, the examination of stomach-contents can now be performed by the general practitioner without elaborate apparatus or the loss of much time, I propose to demonstrate.

The simplest and best test-meal consists of a good-sized hard breakfast roll without butter, taken when the stomach is empty, thoroughly chewed, and washed down with twelve ounces of water. At the end of an hour a stomach-tube is passed and through it the stomach-contents are voluntarily vomited by the patient, aided if necessary by pressure on the pit of the stomach. To favor the passage of the stomach-tube, it is dipped in warm water, held between thumb and forefinger like a pen, and passed in the middle line of the mouth. As it reaches the fauces the patient is directed to swallow, and as he does so the tube is rapidly pushed on into the stomach. The desire to gag is overcome if the patient takes deep breaths during the swallowing and after the tube is in the stomach. The saliva is prevented from running into the receptacle by wrapping a towel around the tube.

The liquid evacuated contains a sediment of more or less digested bread. If fermentation is going on in the stomach, there is a layer of foam on the surface, and the odor is that of butyric and other fatty acids. The amount of mucus present may be estimated by lifting it upon a loop of wire. Five cc. of the filtered contents are placed in a porcelain dish with a drop or two of one-half-of-one-per-cent. alcoholic solution of di-

methyl-amido-azo-benzol. If this becomes pink it indicates the presence of free hydrochloric acid, and this is estimated by adding decinormal sodium hydroxide solution from a Mohr's burette (50 cc.), drop by drop, until the yellow color of the azo-benzol is restored. This occurs when the free hydrochloric acid is neutralized. The number of cc. of sodium hydroxide used indicates the amount of hydrochloric acid present. To the same 5 cc. are added a few drops of one-per-cent. solution of Congo red, and this, if any further free acid is present, turns violet. Such free acid is organic and is estimated by adding the hydroxide until the red color returns. Lastly, a few drops of one-per-cent. alcoholic solution of phenolphtalein are added and the sodium hydroxide continued until the resulting pink color becomes no deeper on the addition of a single drop of the decinormal solution. This represents the combined acid or acid albumin, and the acid salts. As 5 cc. of stomach-contents have been employed, the number of cc. of sodium hydroxide used in each case must be multiplied by 20 to represent the ingredients in 100 cc. If only 2 cc. of contents are used the figures must be multiplied by 50. The sum of the results represents the total acidity.

Normally the return from the test-meal should be 60 to 100 cc., with acidity 50 to 60, free hydrochloric acid 10 to 15, combined acid 40 to 50, no organic acid and only slight mucus. The lactic acid-forming bacilli do not grow in the presence of free hydrochloric acid, so if this is found, lactic acid is not tested for; but if hydrochloric acid is absent and the Congo-red reaction is positive, the lactic acid test must be made as follows: One drop of tincture of iron is mixed with enough water to leave a barely perceptible color, and the liquid divided between two test-tubes. One tube is retained for comparison, and to the other a few drops of filtered contents are added; a yellow color indicates lactic acid. An ether extract of the contents will give the test more clearly and with greater sureness.

If blood is suspected mix 5 cc. of filtered contents with 3 cc. of glacial acetic acid, and add 5 cc. of ether. Shake well, set aside until the ether rises, and pour it off; to this ether add a few drops of tincture of guaiac and then a like amount of peroxide of hydrogen. A dark-blue color indicates blood.

The deviations from normal acidity are due to increase, decrease, or absence of free and combined hydrochloric acid, to great variability in the amount of acidity and to the presence of organic acids. Change in the amount of hydrochloric acid accompanies changed glandular activity, and this may be functional or organic. Persistent increase of mucus points to the latter. Increased acidity is found in hyperchlorhydria, hyperchylia, the hypersthenic type of chronic gastritis, and usually in ulcer. Decrease of acid occurs in functional loss of glandular activity, and in the asthenic form of chronic gastritis. Much diminished total acidity with absence of free hydrochloric acid points to an atrophic condition; and this, if lactic acid is present, favors carcinoma. Marked variations in the acidity in successive examinations suggest gastric neurasthenia, a condition in which the stomach symptoms usually depend on the ingestion of food, but not on the kind of food. In general neurasthenia a persistently asthenic stomach may be expected. Organic acids other than lactic indicate fermentation and are easily recognized by their characteristic sour smell.

An excessive amount of stomach-contents at the end of the hour means either excessive secretion, pyloric or duodenal obstruction, or muscular asthenia. Much fermentation opposes simple hypersecretion, a normal percentage composition favors it. Active visible peristalsis opposes muscular asthenia and favors obstruction; similar evidence is obtained from the absence of splashing two hours after the ingestion of a pint of water on an empty stomach.

The test-meal is, of course, but one factor in the diagnosis, yet at times it may be the only means of determining the intragastric condition and, besides its function in diagnosis, it also gives direct information as to the kind of treatment necessary. Excessive acidity demands food which is non-stimulating or has much affinity for the acid. Appropriate foods would be milk, if well borne, cornmeal, wheat, flaked rice, eggs, game, white meats, and lean fish. A limited amount of starchy food may be allowed, and plenty of water to dilute the very acid gastric juice. Spices should be avoided. Of drugs, 1/25 grain of extract of belladonna twenty minutes before meals tends to lessen stomach secretion without systemic effects. An antacid may be given two hours after meals. If the bowels are loose this may be chalk mixture; if constipation exists, rhubarb and magnesia without ginger. For diminished acidity the dietary may include milk, oysters, sweetbreads, mutton, red meats, soft-boiled eggs, oatmeal, green vegetables, mashed baked potatoes, and toast or stale bread. Each meal may be preceded by a bitter or stimulant, such as infusion of quassia or condurango, or the compound tinctures of gentian, cinchona, and cardamon. In cases of much diminished acidity, it may be necessary, in order to protect the intestines, to aid digestion with a grain or two of pepsin and ten minims of dilute hydrochloric acid, given once or twice during the digestive period. If there is much mucus, early morning lavage may be of benefit; if fermentation is present, lavage at night will often permit comfortable sleep. Atrophic conditions throw the burden of digestion entirely upon the intestines, therefore the food must be such as to be easily evacuated by the stomach and readily digested in the intestines. It may include milk, soups, broths, well-cooked cereals, baked apples, mashed and strained vegetables, and finely-divided light meats. Massage over the stomach, or alternate hot and cold water, and the internal administration of strychnine stimulate the motor

activity and favor the passage of the food into the intestines. Fruits that cause the formation of much gas, or induce looseness of the bowels, should be prohibited.

A suspected ulcer contraindicates the use of the stomach-tube, and in such a case the vomitus may give valuable information. If the stomach-contents are protected from evaporation, the examination may be deferred until convenient, for the gastric juice is antiseptic, and but little digestive change takes place outside the body.

Thus, as has been shown, the general practitioner, with the present simple methods at his disposal, need no longer feel that an amateur attempt to examine stomach-contents is impracticable or valueless.

THE HYDRIATRIC TREATMENT OF TUBERCULOSIS.[1]

By J. H. KELLOGG, M.D.,
of Battle Creek, Mich.

Since the empiric, Priessnitz of Graefenberg, created a world-wide interest in the curative properties of thermic applications by means of water by restoring to health multitudes of chronic invalids whose cases had been considered incurable, it has been known that hydrotherapy possesses marvelous restorative power in pulmonary tuberculosis. Winternitz of Vienna has published most favorable statistics, and Aberg, in an admirable and interesting paper published in 1890, gave an account of a large number of cases successfully treated by hydriatric means which had stubbornly resisted other measures. Numerous other writers have presented papers on the same subject, especially during these last few years, among which the writer desires to call special attention to the paper of his colleague, Dr. W. H. Riley, of the Colorado Sanitarium, Boulder, Colo.

I have made extensive use of hydriatric methods in the treatment of pulmonary tuberculosis during the last twenty-five years, and will endeavor to present in this paper a brief account of the methods which I found especially helpful as curative agents and as palliatives of the various distressing symptoms complicating morbid conditions, which attend this malady in its several stages.

That the natural curative powers of the body are capable of successfully combating tuberculous disease is shown by the fact that the reports of pathological laboratories in this country as well as in Europe show tuberculous lesions in one-half of all the cases examined post-mortem.

The fact that, although nearly all human beings are almost constantly exposed to infection by the bacillus tuberculosis, all do not contract the disease clearly indicates that the bacillus alone is not sufficient to give rise to pulmonary tuberculosis. The soil in which the tubercle germ flourishes best is found in the tissues of a deteriorated organism. And it is without doubt by the lowering of the vital status of the individual, the lessening of his resistance to pathogenic agents, which from a therapeutic standpoint must be regarded as the real foundation of this formidable malady. This statement is based upon two potent facts: (1) It is impossible directly to destroy the tubercle bacilli when they have once obtained a foothold in the lungs without the employment of such measures as will destroy the living tissues as well as the parasitic microbes. For this reason all the methods of treating pulmonary tuberculosis which have been addressed exclusively to the destruction of the bacillus have proved unsuccessful. (2) Even if the bacillus could be destroyed by germicides or by other means, a return of the disease must be expected, for it is practically impossible to escape exposure to infection, and when infection of an organism has once occurred, the fact is evidence that the individual is susceptible to the disease; that is, his vital resistance has been lowered to such a degree, and the defenses of his body so deteriorated, that he is no longer able to resist the invasion of these pathogenic agents.

I hold that the most important thing to be done in dealing with any case of tuberculosis, aside from meeting such indications as are necessary to contribute to the patient's comfort, or to arrest some process likely to prove immediately fatal, is to build up the person's vital resistance, to improve the quality of his tissues, to raise his whole vital status, and to recover, as far as possible, his original ability to resist the invasion of parasitic organisms and to destroy them when they have gained entrance to the body. The healing power of all disease is in the body itself. Disease of whatever character or origin—acute, chronic, idiopathic, traumatic, or infectious—if recovered from, must be conquered by the body itself. The healing power is in the tissues within the body. The blood is the great healing agent. Improved quality and quantity of blood and increased movement of blood through diseased parts are the things most essential to be accomplished in dealing with a chronic malady of any sort. Hydriatric applications afford the most powerful of all means of awakening and increasing vital resistance in the body, accelerating tissue change, blood-making, and all the vital activities of the body which are essential to life and which participate in the defensive and curative processes.

In the eager search for new remedies and methods by which to combat this most formidable of human maladies, it is indeed singular that a method so well tested and proved as hydrotherapy should be almost universally overlooked. All sorts of measures for influencing the pulmonary mucous membrane have been devised, exploited and tested by practical experience and generally found wanting. Moist air, dry air, cold air, superheated air, air medicated with almost every known volatile agent, from the aromatic extract of pine leaves to malodorous sul-

[1] Read before the American Climatological Association, Washington, D. C.

phuret of hydrogen, have been applied to the mucous membrane of the lungs by inhalation, while the important fact that the pulmonary circulation and the respiratory functions not only in the lungs but in the tissues can be far more certainly and powerfully influenced by thermic applications to that wonderful organ, the skin, has been overlooked.

It is pretty well admitted on all sides that the open-air treatment of consumption with proper diet, carefully graduated exercise, especially contact of the body under proper conditions with cold air, constitutes a better means of combating pulmonary tuberculosis than any system of medication. Exercise and cold air are chiefly helpful by their influence upon metabolism and movement of blood. Exercise influences especially the heart and respiratory movements, while cold air acts chiefly through the thermic impressions and the vasomotor changes and metabolic activities resulting therefrom. Patients who are able to exercise freely in the open air, if other conditions are favorable, generally improve, but the elevation of temperature and the tendency to emaciation so commonly present in this disease often interdict exercise and not infrequently require absolute rest. While rest favors the accumulation of residual tissue, it has the great disadvantage that it lessens excretion, diminishes respiratory movement, lessens the general movement of blood in the body, and lowers vital resistance. It is preferable to exercise only because exercise tends to produce elevation of temperature, even in normal conditions, and when the heat-regulating functions of the body are disturbed, as is already the case in a febrile state, even very gentle exercise may produce a very great elevation of the temperature curve. Elevation of temperature likewise gives rise to excessive oxidation of nitrogen, which is still further aggravated by exercise, thus causing muscular wasting and resulting weakness with lessened nervous and glandular activity.

The curative effects of cold applications to the skin are based upon the same principle, and act as do those of exercise and cold air. A cold application at first excites cardiac activity, the heart later being slowed by the increase of arterial tension which quickly follows a cold application. The peripheral heart, the small vessels of the skin and muscles especially are excited to increased activity, opening more widely, while at the same time their rhythmical activity is accelerated.

Thus, the general movement of blood throughout the body is accelerated while arterial tension is elevated. The irritation of cold when brought in contact with the skin raises the nerve tone as well as vascular tone, stimulating all forms of vital activity. It is in this way that the appetite is stimulated by exercise in cold air, by seabathing, by cold impressions made in any way. Pavlow, in his beautiful experiments for the purpose of determining the conditions which influence the secretion of the gastric fluids, showed very clearly the intimate connection between the appetite and the gastric secretion. He observed that the stronger the appetite the greater the amount of secretion. The absence of appetite, especially in febrile conditions, is a clear evidence of a lack of digestive power. There is abundant experimental evidence to support the power of cold cutaneous applications to stimulate the production of hydrochloric acid and gastric ferments. Cold applications to the skin likewise stimulate respiratory activity. A dash of cold water upon any portion of the body, especially upon the chest, produces very deep involuntary inspiration by exciting the respiratory centers. After a general cold application or the application of a cold chest compress, there is a marked increase in the depth of the respiratory movements for a considerable length of time. The amount of tidal air may be increased, as shown by my own experiments with the cold towel-rub, immediately after the application 33 per cent., forty minutes after 10 per cent.; wet sheet-rub immediately after 36 per cent., thirty minutes after 12 per cent, and an hour after 8 per cent.; the chest-pack, immediately after 33 per cent., thirty minutes after 18 per cent., and an hour after 4 per cent.; and cold mitten-friction immediately after 39 per cent. and thirty minutes after 8 per cent., on the respiratory volume. The respiratory quotient is also increased, showing the enormous increase in the absorption of oxygen by the blood and the oxygenation of the tissues.

Hydrotherapy is thus not only a powerful ally of the open-air treatment of pulmonary tuberculosis, acting as an adjunct of exercise, sunlight, cold or cool air, proper diet, and other hygienic conditions and physiological measures, but it is actually indispensable in a large number of cases in which the patient is so feeble, either from loss of blood or reduction of strength by some other cause that the advantages of the open-air method are only in small part available. In these cases hydriatric measures properly adapted to individual cases serve as a substitute for cold air and exercise and have the advantage over both these measures in the fact that they are capable of absolute regulation and graduation, awakening within the system the same reactions more or less ample and intense as may be desired and thus serving as a means by which the patient may be lifted from a state of utter helplessness by daily increments of energy until he becomes capable of utilizing with advantage more vigorous measures.

Hydrotherapy is of special value during the hot months of the summer season, which are exceedingly trying to the tuberculous patient, as a means of antagonizing the debilitating effects of heat. Observations with Mosso's ergograph show that extreme muscular and nervous exhaustion resulting from the hot bath may be instantly removed by a cold application. Not only is the depressing effect of the hot bath wholly antidoted by the succeeding cold application, but the output of energy may be raised even above

the normal level. During the winter months when out-of-door exercise is in many localities not infrequently prohibited for weeks at a time by inclement weather, except in cases of those who have been systematically trained to endure contact of the cold bath, hydrotherapy is invaluable as a substitute for the tonic influence of cold air and exercise.

Hydrotherapy affords the most valuable of all known means of training the skin. General cold applications may be properly termed "vasomotor gymnastics," in which not only the skin but the vasomotor centers controlling the cutaneous circulation are brought into vigorous exercise. By the daily repetition of the cold bath systematically graduated from higher to lower temperatures,

COLD MITTEN FRICTION.

Fig. 1.

the ability of the skin to react quickly to thermic impressions may be enormously increased. A healthy well-trained skin contracts vigorously when a cold impression is made upon it. Not only the blood-vessels, small arteries and veins, but also the lymphatics, even the capillaries, and all the muscular structures of the skin contract, thus lessening the blood-supply and preventing the undue cooling of the blood which gives rise to chill and taking cold. In no class of cases is this training of the skin and the protection which it affords more necessary than in cases of pulmonary tuberculosis. The cold bath affords the only means by which this training can be accomplished, and hence it is indispensable to the rational treatment of this malady.

Cold water is a physiological tonic and has the advantage over medicinal tonics of all sorts in that it awakens nervous activity without the imposition of any extra burdens upon any vital organs and without hampering the activity of any function. The cold bath employed in such a manner as to produce tonic effects accomplishes its results by increasing vital resistance to the causes of pathological processes by making the wheels of life run more smoothly, by lifting the whole vital economy to a higher level. The impression made upon that harp of a million strings —the skin, with its vast network of sensory, motor, sympathetic, vasomotor and thermic nerves, arouses every nerve-center, every sympathetic ganglion, every sensory and motor filament in the entire body to heightened life and activity. Every blood-vessel throbs with quickened impulses, the whole being is translated into a new state of existence.

A person who has never experienced the glow of exhilaration, the invigoration and buoyancy of body and mind which accompany the state of reaction from a short, general cold application, cannot well appreciate the value or significance of the cold bath as a physiological stimulant. It is not too much to say that it is of all measures known to man the most valuable as a means of arousing to activity the flagging energies of the body and of lifting the enervated invalid out of the organic and functional disorders of chronic diseases.

The tonic effects of cold water are unquestionably, to a large degree, due to the influence of cold impressions acting through the nerves of the skin upon the sympathetic nerve-centers. The awakening of the sympathetic to renewed activity, or a balancing of its action, is what is especially needed by the great majority of chronic invalids. The functions of the brain and spinal cord, and through them all forms of nervous activity are, to a considerable extent, influenced by the sympathetic. The sensation of well-being which accompanies the reaction following a general cold application is largely due to the increased activity of the cerebral circulation brought about through the stimulation of the sympathetic. By its power to influence the sympathetic, hydrotherapy is capable of controlling, reorganizing, balancing, all the processes of organic life, and through them, modifying the functions of animal life to a marvelous degree.

The methods by which the powerful restorative effects of water may be obtained are exceedingly simple. They do not require elaborate apparatus or hospital appliances, although they do require the use of judgment and discretion in their application.

The general method pursued by Aberg consists in the application of cold water, the intensity of the application being systematically increased. Aberg divides his hydriatric applications into three grades, which may be briefly described as follows: (1) Bathing of the face, neck, and the anterior and posterior surfaces of

the chest with a sponge dipped in cold water and wrung dry. The application is at first very short, and is immediately followed with drying and friction of the parts. The patient remains

WET SHEET RUB. (First Step.)

Fig. 2.

covered in bed or exercises in the open air until reaction is complete. The application is first made but once a day—in the morning. Later both morning and evening, the sponge wrung a little less dry each day. (2) Cold water is poured over the head, neck, face, back and breast of the patient from a watering-pot, each part being gone over one or more times as the treatment progresses. The parts are then dried and rubbed as before, and reaction promoted by rest in bed or exercise. (3) Immersion of the whole body in the full cold bath, followed by immediate drying with vigorous rubbing. The bath is of very short duration (2 to 6 seconds).

Ice-water is used for the sponging and sprinkling with a watering-pot. Water at a temperature of 45 to 54° F. is used for the full bath. Aberg claimed for his method the suppression of the night-sweats and fever within a few days after the beginning of treatment in most cases, and a notable increase in appetite and body-weight, often very rapid and marked, and improvement in all respects.

The method of Winternitz is somewhat less heroic than that of Aberg. He employs ablution in place of sponging and wet sheet-rubbings (45 to 48° F.) in place of the sprinklings; and the cold rain-douche or plunge-bath at 54 to 58° F. Winternitz employs also the chest-pack, of which Aberg seems to make no use.

The method which I have formulated and from which I have seen excellent results differs somewhat in detail, although not in principle from that pursued by Aberg and Winternitz. Four different sets of procedures are employed for producing general effects, each of which is capable of being graduated to any degree desired. These are as follows:

1. Dry friction of the whole surface with the naked hand or with the hand protected with a friction-mitt. The friction should be continued until the surface is warm and vigorous cutaneous circulation well established. The dry friction is followed by friction with the hands dipped in water at 60° F. The temperature of the water is lowered one or two degrees each day until ice-water is used, and the number of dippings of the hand in the water is each day increased. The parts are carefully rubbed, then dried, and rubbed with the hand until warm and red. This application should be made twice a day, in the morning before the patient rises and at night after retiring.

2. Cold, wet friction with the friction-mitt (Fig 1) dipped in water, extending over the whole surface of the body to be applied first,

WET SHEET RUB. (Second Step.)

Fig. 3.

once daily, preferably in the morning, later, twice a day, in the evening as well as in the morning, application being substituted for the wet hand-rubbing. The application should be made

to small areas of the skin in succession, each part being rubbed until red, then well dried, and rubbed with the hand before extending to another area. The patient should not be allowed to become chilly. The temperature of the water should be at first 60° F. and then should be gradually lowered from day to day until ice-water is employed. The rate at which the temperature is lowered may vary from one to two degrees daily to three or four degrees, according to the susceptibility of the patient. The patient, if feeble, should remain in bed until good reaction has occurred. If strong enough to do so, the patient should walk after treatment for fifteen to twenty minutes, or exercise moderately for an equal length of time in a gymnasium to promote reaction. If the reaction is not complete, pul-

WET SHEET RUB. (Third Step.)

Fig. 4.

monary congestion, cough, and other ill-effects will be apparent. The feet and hands, as well as the general surface of the body, should show good reaction, as indicated by warmth and natural color. Coldness of the hands and feet after the operation indicates defective reaction and requires heating processes of some sort, as short fomentation to the spine, or warming of the hands and feet by means of rubber-bags filled with hot water, or immersion in hot water for a few minutes before the application and more thorough rubbing in connection with the cold application (Fig. 2).

3. The wet rubbing-sheet at 60° F., the temperature being gradually lowered to 50° F. This application is best made in the morning when the patient rises warm from the bed. It should be taken in a warm room. After the application, if the patient is feeble, he should return to bed and remain there until thoroughly warmed, but, if strong, he may exercise moderately for fifteen to twenty minutes to promote reaction. The duration of the application should be one to three minutes. If the patient's temperature is subnormal in the morning, the application should be made later, as at 10 or 11 A. M. It is well in such cases also to precede the cold application by heating the skin by the sun-bath, the electric-light bath, or the skin may be warmed by dry friction.

In the absence of other measures an improvised vapor-bath may be employed for two to three minutes, or the patient may be subjected to the action of a warm rain-douche, a hot full bath (104° F. for three to five minutes), a hot foot-bath, or a fomentation to the spine or abdomen. Great care must be taken to avoid sweating and overheating. The heating process should not last more than three to five minutes. If reaction is deficient, the patient may, for the first applications, stand in a hot foot-bath of 104° F. during the application of the cold sheet. To prevent congestion of the lungs under a general cold application, the chest should be rubbed with the dry hand or the friction-mitt until red before the application is made. The attendant applies the hand, after dipping the hand in ice-water, to the chest before and behind a few times with vigorous rubbing. The duration of the wet sheet-rubbing should not be more than thirty or forty seconds at first. The time may be gradually extended to two minutes. Two persons should be employed in administering the treatment, one to rub the legs, while the other is rubbing the arms and trunk. Great care should be taken to avoid chilling by evaporation, either before or after the rubbing. To prevent this the patient should be wrapped in a woolen blanket until everything is in readiness for the application of the wet sheet. Then as the woolen blanket is withdrawn the wet sheet is applied as shown in Figs. 2, 3, and 4, and the procedures already described carried out with vigor and with discrimination.

4. The fourth procedure begins with the warm rain-douche, temperature 100° F., for one minute, while a hot spray, 110-120° F., is applied to the legs for the same length of time. The application terminates with the cold rain-douche, 60° F., for ten seconds. The duration of the application should be gradually increased to 30 seconds. Immediately after the application the patient should be wrapped in a Turkish sheet and thoroughly rubbed by two attendants until reaction is well established. Complete reaction should be secured by wrapping in blankets for a few minutes, or by moderate exercise.

[To be continued.]

BRONCHIAL DISEASE NOT INVARIABLY A CONTRAINDICATION FOR ETHER ANESTHESIA IN ABDOMINAL SURGERY.[1]

By THADDEUS A. REAMY, M.D.,
OF CINCINNATI, OHIO.

My personal experience in surgical anesthesia embraces some 8000 cases, representing minor and major operations done by me in private houses, private and public hospitals. Ninety-four per cent. of the patients were women. My obstetrical work comprises more than 3000 deliveries, 2000 of these under chloroform anesthesia. As a rule, it was not employed until the second stage of labor. This reference to obstetrical work is incidental, since it is, of course, not included in the 8000 cases. It may, however, show that I have not presumed to speak without the authority of some experience upon the general subject.

So convinced am I of the greater safety of ether than of chloroform as an anesthetic in surgical work that in later years I uniformly selected it except in the presence of strongly marked contraindications—serious disease of the kidneys or of the respiratory organs. I have never lost a patient under ether or chloroform, although I have on several occasions witnessed very unsatisfactory symptoms.

In this brief clinical note I shall not discuss the general question of anesthesia. What I say applies to ether alone. Preparation of the patient and methods of administration must be briefly considered, because these matters are, in my opinion, vital to the desired results. Except in emergency cases I order free cleaning out of the bowels for a woman upon whom I am to make either abdominal or vaginal section. This is done by a saline purgative the day before the section, after which she must take no solid food. She is given coffee and cream three hours before the section, and four grains of calomel an hour before. Unless there are contraindications she is given morphine, gr. 1/6, and atropine, gr. 1/20, twenty minutes before the commencement of the anesthesia.

The ether is administered in the operating-room, with the patient on the operating-table. The temperature of the room should be 98° to 100° F. In all cases of weak heart, or where there is bronchial trouble, the table should be in the modified Trendelenburg position—*i. e.*, the chest of the patient should be six to eight inches lower than the pelvis and lower extremities. A hard pillow, some three or four inches thick, should incline the head forward, so as to facilitate free respiration, and to some extent guard against the falling back of the tongue during anesthesia. This position also favors the escape of mucus and broken epithelium, which may be very abundant, especially in patients suffering from bronchitis, when anesthesia has continued for some time. Nothing which has been said as to position relates to the surgical aspects of the case. If the full Trendelenburg position is desired, very well. Even in that position it is better if the head is carried slightly forward for reasons already named.

Quality of Ether. This is of prime importance in all cases. It is, if possible, still more important when the patient has bronchial or kidney disease. Impure ether is responsible for much of the danger attending anesthesia, for the undue irritation of the respiratory passages and for the nausea that follows an operation. For years I have avoided all anxiety as to quality of the ether used by ordering Squibb's anesthetic ether in one-quarter and one-half pound cans; pouring it direct from the cans into the inhaler, thus guaranteeing its purity and freshness. There may be other manufacturers equally successful, but as Squibb's ether has never disappointed me I have not changed.

Method of Administration.—This I consider important both as to immediate safety and subsequent results. It is certainly of great moment in patients with bronchitis. I greatly prefer the closed inhaler, if it is so constructed as to secure the ends in view without compromising disadvantages. Such an inhaler I here present. It is constructed simply of several thicknesses of paper, such as newspapers are printed on, cut and stitched together. It is so shaped that when placed over the face it includes the chin and nose. Two sizes are made, to fit large or small faces. It is covered by a slip or case made of thick muslin. This fits accurately. The free end of the slip must be long enough to reach, when applied, below the absorbent cotton, which is packed closely in the inhaler and upon which ether is poured to saturation at the commencement of the session. As a rule, no more ether is added unless the operation continues longer than forty minutes. The inhaler is made by my nurses and requires but a few minutes to construct. It is cheap and simple. In no case is the absorbent cotton used the second time, and in no instance is the case of muslin to be used again until it has been washed and sterilized by the same treatment as that given my gauze sponges. The paper cup may be used repeatedly, only requiring to be sterilized by hot air. During the inhalation the anesthetizer places the hood closely to the face, holding it in position by compressing the two sides firmly against the bridge of the nose with the index finger and thumb of one hand, while with the fingers of the other hand the opposite wall of the inhaler is pressed against the chin. Thus the inhaler fits rather snugly at every point.

A very small quantity of atmospheric air will, however, pass continually through the texture of the inhaler, and a small quantity will pass in about the bridge of the nose. The quantity of air can readily be increased at this point without removing the inhaler, should evidence of cyanosis demand it. It should have been noted that there is a considerable space in the inhaler, when applied, between the nose and mouth of the pa-

[1] Read before the American Gynecological Society, Washington, D.C., May 2, 1900.

tient and the cotton containing the ether. This is a reservoir for the ether vapor and the carbon dioxide, which in a warm state is being inspired. This mixture is, of course, mechanical, not chemical. The relative proportions of the agents are constantly modified by the conditions of the patient, the profoundness and the duration of the anesthesia.

I consider this mixture desirable for reinhalation from a moderately close inhaler. First, because it is far less irritating to the respiratory mucous membrane either in the pharynx, larynx, trachea, larger or smaller bronchi; second, such a mixture has the dual action of stimulating the capillary circulation in these membranes, so as to modify the character of congestion present in acute, subacute, and chronic bronchitis when present, followed by rapid relief in crisis by expectoration, and the sedative action sought by the use of other remedies in such cases, but too often sought in vain; third, the quantity of ether necessary to secure anesthesia for a given length of time is greatly diminished. This avoids an element of positive immediate danger, that of overcharging the system with ether, thus endangering the respiratory and cardiac centers. It also guards against possible damage to the kidneys, relieving them from the necessity of the removal of an excessive amount of ether subsequent to the operation. The same may be said of the lungs, through which also a good proportion of the ether which has been absorbed must be removed. My clinical observations justify me in saying that in properly selected cases ether anesthesia, instead of aggravating bronchial disease when it exists, or of exciting it in cases when it does not exist, becomes, when properly managed, a most valuable curative agent.

Within the past five years I have had evidence that bronchial disease was seriously aggravated by ether in but a single patient. But I must be more specific as to the method of administering. It is important that the patient is tranquil, not excited by fear. She will have confidence in no one so much as the surgeon who is to operate. It is my custom in private and in private hospital practice to administer the ether myself until unconsciousness is secured. If proper asepsis has been observed my hands can be sufficiently cleaned again in a minute so that I may proceed with the operation. Before the inhalation is commenced I seat myself near the patient and speak to her words of kindness and of assurance, asking that when she commences the inhalation she will breathe naturally. It is wrong to ask the patient to breathe deeply. Shallow breathing at the start will go far to avoid the reflex coughing excited by irritation at the tracheal bifurcation. The inhaler is held two or three inches from the face until five or six inspirations are made; it is then placed closely over the face and continued until reflex coughing occurs. Usually this will not take place until after a number of inspirations, in some cases not at all. When coughing and resistance occur the inhaler must be removed far away so that unmixed air can be breathed. When quiet is restored the inhaler is reapplied, and the patient, who is of course yet fully conscious, is requested to avoid resistance. After four to six inspirations with the inhaler near the face it is now placed closely down when usually no further coughing or resistance will occur.

In the last series of 100 consecutive cases anesthetized in my private hospital prior to my sale of the hospital, of which accurate records were kept, the average time required for complete anesthesia was six minutes—in many cases it was accomplished in four minutes. Struggling was rare, indeed, and not in any patient did damage of the lung or kidney follow. It has already been stated that if the cotton in the inhaler is saturated at the commencement full anesthesia will be sustained usually for forty minutes without adding more ether. Of course, the inhaler must be constantly applied, as it should be, unless some symptom should demand that the patient have fresh air. If the operation requires more time more ether must be added; but when added caution must be observed lest the patient, whose system is already well charged, receives an overquantity. Thus, notwithstanding the cotton is again filled to saturation the inhaler must not be held too closely over the face until the effects are observed. The frequent additions of small quantities of ether to the inhaler, awaiting resistance of the patient as a signal for more, is mentioned only to be condemned. It is not the quantity of ether placed in the cotton which is to be considered but the quantity that enters the circulation. Of course, the administration of ether from a close inhaler, so that the patient reinhales the vapor mixed with carbon dioxide, is neither new nor novel. It is advocated by many and condemned by more. But as far as I know, excepting the fact of the lessened amount of ether required, and the extension of the practice to include cases of bronchial disease, the reasons for such practice have not been advocated as the clinical facts warrant, nor have the details of conditions essential to the best results been urged with sufficient emphasis.

I am also aware that Clover's inhaler and others are constructed for reinhalation. These I have used frequently, but my objection to such inhalers is that the admixture of the ether and the carbon dioxide does not commence at the commencement of the session and is not automatically continued—also that the quantity of atmospheric air admitted, if any, is not regulated. Again, such an apparatus requires more skill and judgment on the part of the anesthetist. Finally, the inhaler is cumbrous to carry about and difficult to keep clean. The inhaler which I show you is too simple to be called an inhaler. It is simply a modification of the old paper cone and sponge, but it has essential differences in principle.

In my private work the anesthetic is, as a rule, administered by one of my nurses with my as-

sistance and under my supervision as already noted. I am aware that this course is open to criticism. It should be remembered, however, that I do not impose the custom upon others. Finally, notwithstanding the increased blood-pressure in the earlier stages of ether anesthesia, and notwithstanding the high temperature of the air in the operating-room, at the close of the operation, especially if it has been prolonged, the body temperature of the patient is now reduced one-half to one degree; the capillaries are relaxed, and she is bathed in perspiration. It is therefore plain that the greatest caution must be taken in removing her from the operating-room to her own room. I have often seen patients, with insufficient clothing, wheeled through cold corridors after operation. Thus often is occasioned the bronchitis, pneumonia, or kidney disease falsely attributed to ether.

The following cases, briefly abstracted from my private hospital records, may illustrate the subject.

Case I.—Miss F. C., aged twenty-eight years, entered my private hospital January 9, 1895. Had been under my observation and care for a year. Had suffered from unbearable dysmenorrhea, and had had two attacks of pelvic peritonitis; was now having occasional attacks of hystero-epilepsy. She and her friends were anxious to have the ovaries removed. During the past six months she had suffered from bronchial cough. For the last six weeks the expectoration was characteristic and copious. Patient had lost twenty pounds in weight. After proper action abdominal section was made and the ovaries removed January 28, 1895, assisted by Drs. C. L. Bonfield and Edward Mitchel. Left ovary enlarged and cystic; the right hard, half-size; extensive adhesions. Ether was administered with the patient in the Trendelenburg position. Frothy mucopurulent discharge through the mouth and nose during anesthesia was very abundant, causing much embarrassment and prolonging the time required for securing unconsciousness to nine minutes. The position of the patient, however, facilitated the escape of this secretion. The operation lasted, including closing of the abdominal wound, thirty minutes. Temperature at the commencement of anesthesia, 99.5° F., at the close of the operation 98° F. Recovery was uninterrupted; cough and expectoration continued for ten days, but rapidly diminished after the second day. The patient was allowed terraline and sherry wine for the cough. Temperature was at no time after the operation over 101° F. Within six months the patient had gained twenty pounds; has now gained thirty-four pounds. Health perfect.

Case II.—Mrs. F. H., aged thirty years, entered my private hospital February 11, 1898; married nine years, no children; one abortion seven years ago. Had menstruated regularly, but during the past year had noticed at irregular intervals discharge of blood from the vagina; recently it has been more profuse; odor and pain were absent. Patient has lost in weight and is anemic; has distressing cough, which has continued during the past month, but with little or no expectoration. This morning, however, after a journey of 150 miles by rail, expectoration of frothy mucopurulent matter is rather abundant. She has a temperature of 100° F.; pulse 90.

Examination of the chest shows moist râles, with gurgling squeaking, etc. Expiration prolonged. No dulness on percussion. Mucous membrane of fauces and pharynx thickened and redder than normal. Diagnosis: Bronchitis, second stage.

Examination of the pelvic organs shows vaginal portion of the cervix half destroyed by carcinoma; uterus freely movable; no perceptible involvement of glands. Decided upon vaginal hysterectomy, to be done as soon as the bronchial difficulty and general condition would justify operation under the approved general treatment. The patient did not improve; cough was distressing, expectoration now occasionally showing streaks of blood. Vaginal disinfectants and astringents per vaginam kept up. Loss of blood from the uterus increasing. Decided not to wait longer. Removed the uterus by vaginal section on February 16th. Four clamps; no ligatures. Present and assisting Drs. C. L. Bonfield and William Gillespie. Ether until unconsciousness, administered by myself, then continued by Miss Pullen, the head nurse. Time required for full anesthesia twelve minutes, as the cough and expectoration were very annoying. Much frothy mucus, some of it well colored with blood, was discharged. During administration the patient was in the Trendelenburg position, but head elevated somewhat. Not any vomiting after operation. At the close of the operation the temperature was 99° F.: at the commencement of inhalation it was 100° F. The patient reacted well and made a speedy recovery. The temperature at any time after the operation was not over 101° F. The cough and expectoration yielded as if by magic; she had absolutely no cough after the second day. The bronchial symptoms never returned. A report from this woman one month since shows her in perfect health; she has gained thirty-five pounds in weight.

My record shows a number of cases anesthetized and operated on when bronchitis in the first stage, acute form, was present, with the result of arresting cough and destroying the mucous congestion present; but the length of this paper forbids my giving further details or recital of cases.

Finally, I reiterate the statement that my clinical studies justify me in the belief that in properly selected cases ether inhalation is positively curative of bronchitis. That its action in these cases is largely local I have no question. To avoid unpleasant complications and to secure the desired results, the following points are essential: (1) Proper preparation of the patient. (2) Preparation of the operating-room with a tem-

perature of 98° to 100° F. (3) Pure ether. (4) A proper inhaler. (5) The proper methods of administration. (6) Due caution against exposure in removing the patient from the operating-room to her own room. The temperature of her own room should not be below 80° to 90° F. for several hours after the operation. (7) Proper care of the patient during convalescence. She should be permitted to drink large quantities of water and should keep the bowels freely open.

CLINICAL MEMORANDUM.

PERSISTENT SLOW PULSE.

By JAMES J. WALSH, M.D., Ph.D.,
OF NEW YORK;
INSTRUCTOR IN DISEASES OF THE CHEST AND GENERAL MEDICINE IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

Cases in which the pulse-rate remains persistently below forty are so infrequent as possibly to lend interest to the following case. The patient is a woman, aged thirty-one years, who has enjoyed very good health since childhood, except for an attack of grip about ten years ago when that disease was making its preliminary impression upon the American people and American medicine. The attack was not very severe, but during its course her physician called her attention to the fact that her pulse was very slow. Even during the occurrence of febrile temperatures, it did not reach sixty to the minute. Observations made after the attack of grip showed that her pulse remained persistently at about forty or under.

In the beginning of April of this year she came for treatment for loss of appetite and general indisposition. On examination her pulse was found to be thirty-six. Careful examination of her heart showed that this was also the number of the heart-beats. She has now been under observation for over three months and her pulse-rate has always continued about the same. After a rapid walk of over a half mile to the office it rises to 39 or 40, but it has never exceeded that. She considers herself in good health and is able to do considerable housework. Her duties require her to be on her feet most of the day and her work is rather exhausting. She has to go up and down stairs frequently but does not experience much difficulty. Her respirations are somewhat hurried. She breathes normally 22 to 24 times to the minute. The urine is normal, the arteries show no signs of arteriosclerosis, the liver is not enlarged and the organic functions are not disturbed by her slow pulse. Despite a pulse-rate of 36 she is by no means phlegmatic in temperament, but on the contrary is nervous and high-strung and inclined to be excitable.

Her family and early history do not seem to throw any light on her present condition. Her father is dead. Her mother is living and well and two brothers and two sisters are in good health. The other members of the family do not exhibit this phenomenon of slow pulse, at least as far as can be learned. Her mother often said that the patient was the healthiest of her children, but she had all the diseases of childhood and there was a family tradition to the effect that if a contagious disease existed in their neighborhood she was sure to catch it. She was lively and active as a child and played and jumped rope quite as other children did. Dancing was a favorite amusement later in life and some years ago, when the skirt dance was popular, she frequently danced it for the amusement of friends. After her husband's death and when it became necessary for her to earn her own living, she was on the stage for a time and danced without any embarrassment of the respiratory functions. She frequently danced in drawing-rooms and at private entertainments. It is only during the last two or three years that she has noticed that dancing has proved so exhausting to her that she has had to give it up almost entirely. In general, however, she considers herself as able as any one else for the duties and amusements of life. Under the administration of an ordinary stimulant tonic her digestive symptoms disappeared and her feeling of general good health returned. She complains somewhat of shortness of breath, especially when she ascends rapidly more than one flight of stairs. She has been warned of the danger involved in such overexertion. For this symptom of shortness of breath on exertion atropine, 1/200 of a grain, three times a day, gradually increased until she was taking 1/100 three times a day, had a beneficial effect. The drug had no effect upon the pulse-rate, but it seemed to slow and somewhat deepen the respirations.

The interesting question is whether the present case is one of natural slow pulse, the condition having existed all her life, or whether her pulse-rate of 36 has been acquired. The fact that there is no family history of slow pulse speaks against its congenital origin, although not very strongly. Direct heredity is sometimes an element in the occurrence of slow pulse, but is by no means a necessary implication of its occurrence or non-occurrence. The fact that the patient had all the ordinary diseases of childhood without her attention being called to the presence of a slow pulse seems to show that in her early years the slow pulse did not exist. It has been pointed out in a number of cases that grip may cause a slow pulse that persists for months and sometimes years after recovery. Not many cases are reported in which the slow pulse has persisted as in this patient for over ten years. It now seems probable that her present pulse-rate will continue throughout life.

Just what the lesion may be in a case like this is an interesting subject for speculation. Persistent rapid pulse has been set down by one enthusiastic theorist as due to a discharging or irritative lesion of the nucleus of the accessory fibers of the vagus nerve. In the same way we might say that the condition we have to do with

here is due to an irritative lesion of the inhibitory fibers of the vagus nerve. In either case the carefully-evolved hypothesis does not add anything to our knowledge of slow or rapid pulse and lacks the confirmation of a pathologic basis.

For cases like this the term bradycardia, or as Osler, following Riegel, prefers to call it, brachycardia, is sometimes employed. The name was invented as an analogue of tachycardia. It seems worth while to recall, however, that, as Clifford Allbut says, the status of bradycardia is very different from that of tachycardia. In tachycardia there is an affection that occurs paroxysmally, endures for a certain length of time and then is followed by a return to the normal pulse-rate. For what is known as essential tachycardia there is no well-defined cause and no definite pathologic lesion. The heart gradually or suddenly begins to beat two or three times as fast as before, and then after some hours or days returns to its normal condition. Slow pulse, however, is present as the result of some physiologic or pathologic condition. It endures as long as the cause continues to act and then ceases, usually not to return until the same cause gives occasion for it again, or it endures absolutely throughout life. Physiologically it occurs after childbirth. Pathologically it is seen during convalescence from the infectious diseases, as the result of brain tumors or abscesses or because of reflexes from organs to which are distributed peripheral terminal fibers of the vagus nerve. The most frequent cause of slow pulse is gastro-intestinal disturbance. Functional or organic cancer of various portions of the digestive tract frequently give a pulse below 60.

All of these affections characterized by slow pulse are very different from the condition known as tachycardia. The slow pulse in this patient will probably endure throughout life and there seems no good reason for calling it anything more than persistent slow pulse. A number of cases with a pulse-rate below 50 have been reported in which the condition was congenital. In none of them was there any discernible heart lesion. Some of the individuals were able to bear the strain of a good deal of exertion. One of them was a very successful English athlete. It is to be remarked, however, that this athlete died as the result of a so-called cramp while swimming. Other evidences of lack of resistive vitality are not wanting in similar cases. It is probable that the prognosis of these cases of slow heart is not very favorable. Statistics on the subject, however, are very meager and a more careful reporting of such cases seems desirable.

MEDICAL PROGRESS.

Plague Sputum.—That the sputa of plague patients suffering from primary or secondary pneumonia contain numerous virulent Yersin bacilli is a well-established fact. The persistence of this condition during convalescence has recently been investigated at Oporto by Dr. Métin. Sputa were obtained from eight pneumonic cases at various periods and injected into guinea-pigs. The results of these experiments indicate that the sputa retain their virulence for eight or nine days after the subsidence of the fever and then rapidly become harmless. All the animals inoculated within the first eight days succumbed to uncomplicated plague; those inoculated a day or two later became sick, but recovered; and those that received still later injections manifested slight or no ill effects. In view of these results the doctor considers it safe to regard the sputa as non-contagious ten days after the beginning of apyrexia. Experiments were also made with the blood-serum of patients convalescing from plague, who had not received treatment with antipest serum, for the purpose of explaining the infrequence of reinfection. Guinea-pigs inoculated with the blood-serum and, shortly thereafter, with a virulent culture of plague bacilli all recovered after comparatively mild illness. One pig which received the serum twenty-four hours after the culture died in ten days, the control animal having succumbed in three. Experiments on mice with older serum were less successful, although the animals all lived from one to thirteen days longer than their respective controls.

Hemorrhagic Grip Epidemic.—V. Grossule (*Gazz. d. osp. e delle clin.*, No. 27, 1900) gives the result of his observations in an epidemic of influenza, affecting seventy per cent. of the inhabitants of a rural district in Italy, where previous to the epidemic, only two or three cases of pneumonia were observed in a population of over two thousand people. During the epidemic nineteen out of thirty-six cases of pneumonia proved fatal; in these cases the hemorrhagic sputum was marked; in a few cases hemoptysis was present. Epistaxis was observed in many cases during the epidemic; some were so profuse as to require nasal plugging. Menorrhagia was a common symptom, even virgins and married women of all ages being affected; some patients previously suffering from amenorrhea sought treatment for the marked menorrhagia which persisted, in one case for seventeen days; in some the uterine hemorrhage was so profuse as to require vaginal tamponading. The frequency of these hemorrhagic manifestations occurring in so many different families and affecting both sexes, independent of age or previous condition, gives strength to the theory that they were caused by the specific poison of influenza.

Ulcer of the Stomach.—Despite active research in the last few years, no satisfactory explanation of gastric ulcer can be given, according to H. Weiss (*Centralbl. f. d. ges. Therap.*, Oct., 1900). Virchow's theory is still adhered to by many and it is conceded that in animals even large defects in the mucosa heal kindly unless a hyperacidity exists—the precise condition which

obtains in man. Pathologically a transection of the ulcer shows absence of the mucosa, remains of glands, thickened intima and organizing thrombi in the arteries, round-cell infiltration and thrombosed veins. In some cases aneurismal dilatation with consequent diminution in the nutrition of the coats has been found, other local disturbances in circulation may sometimes be traced to arterial disease, general visceral congestion or to pressure of tumors on the stomach. Less common etiological factors are trauma and infection, the latter acting by the localization of the infectious agent, by small miliary abscesses developing in the mucosa or by a circumscribed generation of toxins. Bacteria, however, disappear with the development of the ulcer. Apart from the fact that the indications for surgical intervention have been more clearly set forth, therapy can record but few advances. Rest and diet are still the important mainstay in medical treatment. The patient must be kept in bed for ten days. The epigastric area should first be cleansed with alcohol and sublimate, a pad with boric ointment and then a very hot flaxseed poultice applied, the latter to be changed every ten to fifteen minutes. At night a Priessnitz pack is used instead. After the tenth day the Priessnitz pack is used alone for three more weeks. In case of hemorrhage, poultices are not to be employed unless a quarter of a year has passed, instead a Priessnitz pack or an ice-bag is admissible. The patients should sip from one-half to one pint of lukewarm Carlsbad water half an hour before breakfast for four weeks. Sodium bicarbonate with or without bismuth is also good. The diet is slowly changed from liquid to soft and then to non-irritating solid food and in severe cases exclusive rectal feeding may at first be demanded. Another good means of medication consists in washing out the stomach and introducing bismuth, made into a thin paste with water, through the sound. In all cases medical treatment should be tried before surgical. The indications for the latter are (1) hemorrhage, especially the small, long-continued bleedings, but also in case of large loss of blood when these show a tendency to recur; (2) severe pain and frequent vomiting; (3) perigastritis or peritonitic abscesses; (4) acute perforation. The dangers of operation are slight. Of the two methods in vogue, pyloroplasty and gastroenterostomy, both are equally good, but the first-named is the simpler.

On Gonorrheal Arthritis.—It is not so long ago since gonorrhea was looked upon as a slight affection, leaving no ill-effects in its wake. Now it is understood that endocarditis, myelitis, anterior horn changes, myocarditis, iritis, peritonitis, and, most common of all, arthritis, may follow a simple gonorrheal urethritis and seriously aggravate this distorder. B. Rubinstein (*Berlin. klin. Woch.*, Sept. 10, 1900) speaks of four varieties of the arthritis: (1) Gonorrheal hydrops; (2) serofibrinous inflammation; (3) empyema of the joints, and (4) phlegmonous inflammation. The last-mentioned form in particular may be serious. Tendons, sheaths and bursæ are also vulnerable to the poison and bursitis beneath the Achilles tendon is both common and difficult to heal. Attention is drawn to the value of the Röntgen rays in determining to what extent the joint and the bone are involved. The best treatment consists in the administration of potassium iodide internally and the application of guaiacol or creosote vasogen externally, and, for the more severe forms, irrigation of the joint with bichloride, 1-2000, care being taken not to allow any of the solution to remain in the joint. After the wound has healed, massage is to be instituted. The urethritis is to be treated at the same time, though sometimes, with very energetic measures, a lightening-up of the process is observed.

Acute Formalin-Poisoning.—J. Klueber (*Münch. med. Woch.*, Oct. 9, 1900) was recently called to a patient who had by mistake swallowed several ounces of commercial formalin. The man was unconscious, there was marked pallor and cold, clammy perspiration, the respirations were increased, there were râles over the lungs, the temperature, pulse and the various reflexes were normal, and there was neither paralysis nor vomiting. The most prominent feature was the coma, it being impossible to arouse the patient. The next morning the patient awoke several times, but soon fell back into his somnolent condition and anuria set in. At last, toward evening, the coma disappeared, the patient acted as if intoxicated, had some headache, conjunctivitis and the buccal mucosa was reddened. The next morning he was restored to health. Throughout the illness formic acid could be detected in the urine.

Treatment of Typhoid.—H. Eichhorst (*Therap. Monatshft.*, Oct., 1900) says he has tried typhoid serum with absolutely negative results, but has been surprised at the remarkably short and favorable course those cases ran which had received antityphoid extract of Tez. Eichhorst believes in absolute rest to the nervous system. Many minor details, such as darkening the room, are of the highest importance. Baths he gives at 95° F. for from fifteen to thirty minutes twice daily until there is no fever for seven days, then once a day. During the febrile period the nutrition should consist of easily-digested food, leaving little feces. Milk answers this purpose admirably and is especially good since also diuretic. It should be boiled and then placed on ice and every half-hour from two to three ounces are to be taken. If the patient objects to milk, it may be masked in coffee, tea or soup. Some variety may prove beneficial; beef-soup with one or two fresh eggs is excellent to break the monotony. All artificial proteid foods are to be discarded as objectionable to the taste in the long end. There is no objection to plenty of

water; it quenches the thirst and flushes out the kidneys. Strict attention is to be paid to cleanliness of the mouth for which purposs aluminium acetate, 1-100, or chlorate of potash, 1-40, is available. The same routine treatment is continued for the first three days that the temperature is normal, on the fourth, fifth and sixth days a farinacious soup, at first thin and later thickened, is allowed. On the seventh day the patient gets from two to three ounces of finely-chopped raw beef and on the tenth day mashed potatoes and roast veal. Bread is permitted with the meat, at first in the form of zwieback soaked in milk. There may be an advantage in giving small doses of salol during convalescence.

Pharmacology of Jaborandi Alkaloids.—C. R. Marshall (*Brit. Med. Jour.*, Oct. 13, 1900) accepts Jowett's analysis of jaborandi as containing three alkaloids, pilocarpin, isopilocarpin and pilocarpidin. Isopilocarpin has an action similar to pilocarpin, but is much weaker. Pilocarpidin is practically inactive. In a further note on the action of the liquid extract, they show that this preparation of the British Pharmacopœia is extremely variable, that it should be excluded and that, until preparations properly standardized for the pilocarpin and isopilocarpin are introduced, the drug should not be employed.

Hemorrhagic Diathesis in Typhoid.—A. Pinard (*Gazz. d. osp. e delle clin.*, No. 27, 1900) narrates the history of a thirteen-year-old boy, whose family and personal history as to hemophiliac tendency was negative. Three days after convalescence from a mild attack of typhoid fever and directly following the ingestion of a hearty meal the lad was found in a profound state of collapse, with delirium, high temperature, rapid pulse, tympanites, diarrhea and all the symptoms of a relapse of typhoid fever, except that the characteristic eruption was absent; instead, there was an eruption of small discrete red macules not disappearing on pressure, being located on the sternum, extensor surfaces of the arms and inner aspect of the thigh; the eruption soon became hemorrhagic in character, with some confluent patches, the area of which varied from that of a pea to a dime. On the following day there were epistaxes, hemorrhages from the gums, bowel and bladder, all of which were so frequent and so profuse as to leave the patient in a highly anemic condition, with stupor and almost extinct pupil reflexes predominating. Under active administration of ergotine by mouth and subcutaneously in addition to the usual typhoid sponge-baths, the patient began to improve; in two days the hemorrhages had ceased and the boy began to improve, recovering after a lenghty convalescence.

Gall-Stone Impaction.—The differential diagnosis between obstruction in the cystic and in the common duct comprises the following features, states F. A. McGrew (*Phila. Med. Jour.*, Oct. 6, 1900): The cystic duct syndrome is gall-stone colic with pain, rigor, vomiting, fever collapse. The pain is excruciating and referred to the right hypochondriac, umbilical or epigastric regions. The common-duct clinical picture varies only in that the pain is referred to the right hypochondriac, right subscapular or right shoulder regions. If the impaction in the cystic duct is permanent we find tenderness in the right hypogastrium to pressure, soreness and dragging pain in the right side, retention cyst (dropsy) of the gall-bladder which forms a slowly-increasing, palpable tumor in the right side of the abdomen. If the lodgment of the stone in the common duct be fixed there will be also tenderness and discomfort in the right hypogastrium, jaundice, bile in the urine, absence of bile in the stools, fatty, clay-colored, offensive stools, constipation, slight distention of the gall-bladder, enlargement of the liver, pulse slowed to 60, 50, even 40, nervous signs of cholemia. On the other hand, if the offending body be only temporarily arrested in the cystic duct, it may slip into the bladder and manifest its presence solely by attacks of slight hypogastric pain and tenderness with colic and some digestive disturbances. If more than one stone be present or the bladder be distended by them, they can be felt as such or grating sounds heard. If the stone slips into the common duct and there stops the syndrome at once becomes that of its site.

Gall-Stones and Appendicitis.—A. J. Ochsner (*Phila. Med. Jour.*, Oct. 6, 1900) says that during the past few years he has noted the coincidence between chronic appendicitis and gall-stones and *vice versa*. So much so that in many patients in whom the gall-bladder and passages have been diseased he has found the appendices showing proofs of previous attacks of inflammation. Many of these organs have been thickened, adherent, folded and distorted upon themselves, cicatrized, stenosed or containing fecal calculi, thick mucus or even pus. Since many authorities claim that the greatest single agent in the production of gall-stones is infection and since it has been abundantly established that during appendicular invasions the colon bacillus and other intestinal germs are greatly multiplied throughout the intestinal tract and since access to the gall-bladder may be had directly through the upper bowel and the bile-ducts or indirectly through the circulation of blood or lymph from an inflamed appendix, it appears rational to believe that in the foregoing three factors lies the explanation of the concurrence of these two diseases. Again in support of the infection by indirect avenues is the fact that when the common bile-duct is obstructed or ligated in animals the passages and bladder rapidly grow germs, which may very well reach it through one of the roundabout ways above named. His observations are numerically meager, as they cover only three months early this year, the first period consistently devoted to collecting data. Of eighteen cases of gall-stones six had appendicular lesions,

while of sixty cases of appendicitis (including the six above) 10 per cent. had gall-stones. These last observations are not satisfactory, because in a very great number of the acute appendicites circumstances of local and systemic conditions prevented examination of the gall-bladder. His method of exposing both regions is a long vertical opening of the right rectus sheath.

Gastric Motility.—There has been a great advance during the past few years in the perfection of methods for testing the functions of the stomach. A. Macfarlane (*N. Y. Med. Jour.*, Oct. 20 and 27, 1900) says that the numerous neurotic disturbances, so common and so confusing in stomach affections, have very little if any influence on its motor functions. Marked diminution in gastric motility almost always excludes a neurosis, while its presence indicates a serious lesion. The secretory and absorptive powers are not essential to health, as is shown in some cases of achylia gastrica and in total extirpation, but even slight impairment of motility induces marked gastric symptoms, manifested by the dilatation of the stomach and retention of food beyond the normal period. The symptoms are pressure and fulness after eating, rumbling and splashing, nausea, vomiting, epigastric distress or pain, constipation and great thirst. Of these vomiting, especially of food eaten days before, markedly sour and showing three layers, the intense thirst and diminished diuresis are characteristic. To determine the dilatation several methods are used. Inspection may sometimes show peristaltic movements indicating a stenosis and hypertrophied wall. Percussion is frequently helpful. Splashing is important only when obtained several hours after a test-meal. Dilatation by gas forced through a stomach-tube is very efficient. The most reliable sign of motor insufficiency is the presence of food after the normal time. By eating raisins, grapes or berries and swallowing their seeds in the evening and then taking a test-meal in the morning, the motility of stomach may be roughly determined from the presence or absence of the seeds. Or fifteen grains of salol may be given and if it is not detected in the urine until later than seventy-five minutes after ingestion and continues to be present after from thirty to thirty-six hours, then a motor insufficiency is present.

Persulfate of Soda, or Persodine.—After discussing the toxicity, the properties, and the results of numerous experiments upon animals with the persulfate of soda, or persodine, G. Milian (*La Presse Méd.* Oct. 6, 1900) says that the drug, chemically pure in solution, is a substance very slightly toxic and can properly be included among our drugs. Its principle properties are antiseptic, antithermic, aperient and digestive, and an aid to nutrition. Of these properties its aperient and digestive action is most prominent. Secondarily it excites an improvement in nutrition and an increase in weight. Persodine is indicated especially in early tuberculosis, in convalescents from acute illnesses in which the digestive functions are illy reestablished, in chlorotics, in neurasthenics and hypochondriacs who have at the same time gastric atony. The dose of persulfate of soda, or persodine, for an adult is 20 centigrams, or a tablespoonful, in solution in a glass of water. For a child a tea- or dessertspoonful is the dose. It should be taken each twenty-four hours one hour before the principal meal. At the end of three or four weeks the drug should be discontinued to avoid the patient's becoming accustomed to it. Give the drug a little later if the appetite appears to become poor again. Milian says that the only inconvenience from the drug is the appearance, sufficiently rare from other causes, during the first forty-eight hours, of a mild diarrhea which soon disappears. The solution has no disagreeable taste and is easily taken by patients.

Acute Nephritis Following Influenza.—One of the more rare complications of influenza is nephritis. R. G. Freeman (*Arch. of Ped.*, Oct., 1900) cites a number of writers on the subject, giving a résumé of such cases of nephritis complicating influenza as have been recorded, and reports a case of his own. His patient was a boy, four years of age, who had had an attack of influenza during each of the three previous winters. The last and fourth attack presented the usual symptoms for a month, when the patient's temperature rose to 102.5° F. and five days later to 105° F. The temperature then went down until, after four days, it was between 100° and 101° F. On this day the patient passed some very red urine, only about two ounces, which contained considerable blood, 5 per cent. by bulk of albumin, and casts, both hyaline and containing blood-cells. About one week before this the urine had a specific gravity of 1022 and contained no albumin and no blood. The day after the red urine was passed the patient's temperature became normal and remained so, but the boy passed urine only in small amounts, varying from six to fourteen ounces a day. The blood continued in the urine for five days and the casts for ten days. At the end of this time there was no albumin or casts in the urine and it was passed in the normal daily amount of about thirty ounces. No edema was present. The child got well and has had no recurrence of the albuminuria during the following year. Two months later, however, after the child had a slight disorder of the bowels with diarrhea, he passed no urine during one night, and the next morning passed about half an ounce which was very red, specific gravity 1050, and contained considerable deposit. There was no albumin, casts or blood, but a considerable quantity of urates and phosphates present. This boy had, therefore, an acute nephritis of the form which most commonly complicates influenza. On this and a few other cases Freeman bases the fol-

lowing conclusions: (1) Although albuminuria is fairly frequent in influenza, nephritis is a rare complication. (2) The nephritis complicating influenza is clinically of the acute hemorrhagic type and morphologically shows toxic lesions. (3) It apparently attacks children more often than adults. (4) The kidney disturbance may appear a few days after the acute symptoms of the influenza, or as long as a month later. (5) The prognosis is good.

Treatment of Eczema by Red Solar Light.—The favorable results which Finsen has obtained in variola by the action of the red rays of the solar spectrum have stimulated W. Winternitz (*Sem. méd.*, Aug. 15, 1900) to experiment with an analogous treatment in subjects with eczematous lesions. In these attempts the eruptive regions, previously covered with thin silk stuff of an intense red color, were exposed directly to the solar light as long as possible (even as long as four hours in one case). In all the patients treated in this way, whatever the form of eczema that was present, Winternitz noted a rapid disappearance of the symptoms. The serous oozing, the cutaneous hyperemia and the inflammatory infiltration were diminished, then disappeared completely.

Treatment of Ulcerous Acne by Applications of Sea-Salt.—For atrophic or ulcerous acne which attacks most frequently the face and causes the formation of depressed cicatrices, Luithlen (*Sem méd.*, Aug. 15, 1900) has recourse with success to the use of compresses soaked in a one- or two-per-cent. solution of sea-salt applied at night to the affected part. In the daytime these compresses are replaced by a pomade containing from one to two parts of sea-salt to a hundred of lanoline. Under this treatment the ulcers soon became clean, then filled up a little; the infiltrations did not ulcerate again, but retracted rapidly, and no new eruption appeared.

Bubonic Plague.—Owing to the presence of several cases of the plague recently appearing in our large sea-coast cities, all physicians should possess sufficient information in regard to the disease to enable them to make a diagnosis and prevent unnecessary infection. The October *Practitioner* has devoted much space to discussions of this disease. J. Cantile says that the period of incubation is from three to five days. It may begin in one of three ways: (1) A sudden rigor followed by high fever, headache, giddiness, vomiting, epigastric pain, and extreme exhaustion; there may be apathy or delirium. (2) Some cases begin with fever, headache, loss of appetite, but with no mental disturbance. (3) In children convulsions frequently usher in the disease. Buboes may be present from the first, but no superficial glandular enlargement may be present at any time. A frequent picture of an early stage of the disease presents an excited, delirious patient, with features drawn and haggard. The eyes are sunken and injected, with a dusky hue around them. The pulse is full and about 100 or more. Respirations are increased, and hiccoughs or a dry cough may be present. A temperature of 101° to 104° F. is usual, but it may be as high as 107°. The tongue is swollen and the dorsum covered by whitish fur. The abdomen is tender and tense and pain is frequently present. Constipation is the rule. When buboes are present the patient may be sitting up with knees near the chin or lying on the side with the leg in a flexed position. The diagnosis is therefore not clear cut, and pneumonia, typhoid or typhus fever or peritonitis may be the diagnosis at the beginning. Pneumonia may be, however, due to the plague bacillus, this forming one of the types of the disease. Later the tongue becomes shriveled and dry and frequently cracks, assuming a mahogany color. Diarrhea with passages of blood may occur. The circulatory and respiratory systems, except in the pneumonic type, furnish no characteristic symptoms. Three-fourths of the patients have buboes, usually appearing in the inguinal, axillary or cervical region. Unilateral adenitis is the rule. The pain attending the adenitis may be excruciating, but as the mental state becomes affected pressure alone will elicit any response. The plague is usually fatal on the fifth or sixth day. The prophylactic method of treatment is summed up in one word, cleanliness. Haffkine's fluid for inoculation is furthermore a prophylactic of tried value. All persons dealing with plague patients should be inoculated. It reduces the chances of infection by 50 per cent. and the mortality by 80 per cent. Prompt symptomatic treatment and careful nursing are all important. Cathartics and medicines to stimulate the heart and circulation, to procure sleep and to allay delirium are indicated. The vigilance of the health officers in isolating cases and demanding disinfection becomes a paramount necessity.

Food in Zymotic Enteritis.—Milk food of any description is, in the majority of cases, badly borne during the early part of an attack of summer diarrhea. F. P. Elliott (*Bristol Med. Chir. Jour.*, Sept., 1900) says that it must be completely excluded from the diet at the onset and when vomiting is severe all food must be prohibited for twenty-four hours or more. That food must be given, if at all, only in small and oft-repeated quantities is a *sine qua non* in treating the disease. Boiled water or barley-water should, however, be frequently given. Later broths from mutton, veal and chicken, with the fat removed, form the most satisfactory diet. A return to milk should be made slowly, but as soon as possible. When milk continues to cause trouble raw beef-juice is an excellent substitute. The best way to prepare it is to chop up finely raw rump steak and allow it to soak in four times its bulk of cold water for half an hour. The meat is then squeezed in a piece of muslin and the juice extracted. It should be kept cool and freshly prepared frequently. This may entirely replace the proteid of milk for several days.

THERAPEUTIC HINTS.

For Chronic Otorrhea.—

℞ Pot. iodidi..... 1. (grs. xv)
Tr. iodi .....10. (℥iiss)
Alcohol abs.....
Glycerin (pure) ..aa. 15 (℥iv)
Pulv. iodoformi..... 1 (grs. xv)

M. Sig., inject a small quantity of this solution into the auditory canal and down to the tympanum.—*Jour. de Méd. de Paris,* Sept. 30, 1900.

Amyloform.—Amyloform, a new successor of iodoform, over which it has the advantage of not possessing any odor, is a powder which has manifest bactericidal properties, retards the secretions, favors the formation of healthy granulations and does not exercise any irritant action either upon the wound or upon the neighboring tissues. Contrary to iodoform, amyloform can be sterilized in dry or moist heat without being decomposed. Because of this property, amyloform gauze affords some assurances of asepsis which are not found in the other antiseptic gauzes. An emulsion for preparing amyloform gauze is:

℞ Amyloform .... 5 to 10. (grs. lxxv to ℥iss)
Glycerin ..... 10. (℥iiss)
Alcohol ..... 50. (℥xiiss)
Ether ..... 40. (℥x)
Ol. ricini..... 0 gr. 50 (♏ viiss)

The indications for amyloform are the same as for iodoform.—*La Presse Médicale,* Sept. 15, 1900.

Cocaine in the Treatment of Intestinal Worms.—One of the inconveniences attending the use of the anthelmintics ordinarily employed, particularly of extract of male fern, consists of the vomiting following the taking of the medicament. In a case of this kind where the extract of male fern was not well borne by the stomach, Flesch had recourse to the administration, in addition to the male fern, of a solution of cocaine, of which the patient took a few drops from time to time in a little water before and during the ingestion of the capsules of extract of male fern. The solution of cocaine Flesch employed is formulated as follows:

℞ Cocaine ..... .15 (grs. 2¼)
Ext. belladonna..... .20 (grs. iii)
Aqua valerian ..... .10 (℥iiss)

The patient took in all 5 centigrams of cocaine. A purgative, calomel, given some hours later, brought about the expulsion of the tenia. The patient was kept in bed during the twenty-four hours that the treatment lasted.—*La Presse médicale,* Sept. 15, 1900.

Neurasthenia.—Hysteria, being a mental condition, says M. de Fleury (*Revue de Thérapeutique,* Sept. 1, 1900) should be cured by mental treatment, whereas neurasthenia, being the result of fatigue, requires tonic medication and rest. Of first importance is a selected but plentiful supply of food, with prohibition of alcoholic drinks or easily fermentable foodstuffs, and, on account of the poor quality of the gastric juice, but little liquid with meals. When the stomach is empty, however, large draughts of water help to flush out the kidneys and liver, and improve the nervous and mental condition. Baths, spinal douches, electricity, and massage tend to improve the blood and circulation, while the drug-treatment consists of calcium and sodium phosphate, the glycerophosphates, and the saline waters. Such stimulants as caffeine, kola, and their allies should be avoided. Isolation, forced rest in bed, superalimentation by gavage, the method of Weir Mitchell, ought to be reserved for the very severe and rebellious cases. Work, which at the beginning uselessly fatigues the patient and retards his cure, may later on become of much use.

Raynaud's Disease.—The general health must be looked after, writes J. T. Eskridge, and the affected parts well protected from the influence of sudden changes in the atmosphere. The pain may be relieved by:

℞ Ext. cannabis ind..... 0.01 (gr. 1/6)
Camphor. monobrom..
Caffeinæ citrat.....aa. 0.065 (gr. j)
Phenacetin ..... 0.2 (gr. iij)

and, if very severe, by hypodermics of codeine phosphate, 0.065-0.13 (gr. j-ij). Cates recommends nitroglycerin, 0.00065 (gr. 1/100), increased to 0.0013 (gr. 1/50), thrice daily for the relief of the arterial spasm. Massage is useful, with care, lest too vigorous manipulation of the affected parts result in abrasions or gangrene.—*American Text-Book of Applied Therapeutics.*

Tuberculous Knee in Children.—Camille Dupont advises systemic treatment at the outset. Keep limb in good position and immobilize the joint. In the peri-articular type allow walking without a brace, but require a brace in the osseous and synovial forms. For local treatment use compression and injections of camphorated naphtol, with chloride of zinc injections and tunneling of the bone in the peri-articular type. During convalescence allow the patient to walk slowly, and give gentle massage and salt baths.—*Journal de Médecine de Paris.*

Epilepsy.—The epileptic, being a depressed individual, is subject to digestive disturbances, so, by De Fleury's method of treatment, no water is allowed with meals, and the diet is such as to prevent gastro-intestinal fermentation. To eliminate toxic substances moderate exercise, purgatives, diuretics, and diaphoretics should be employed. Hydrotherapy, salt baths, massage, etc., with normal salt injections, are of benefit. Whatever affects arterial pressure may precipitate an attack. Combined bromides lower excitability of the cerebral cortex, and in nocturnal cases are given in large doses at bedtime. The author recommends quiet life in country villages.—Rommé in *La Presse médicale.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinica Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, NOVEMBER 10, 1900.

THE ABATEMENT OF A COLOSSAL NUISANCE.

To the many in the profession, who for years have impotently nursed their outraged feelings at the constantly-increasing disfigurement of the landscape by both lay and medical advertisers, it will be a comfort to learn that a widely-organized effort is about to be made by the American Park and Out-Door Association to abate the nuisance. This society's plan of action, as outlined by the secretary of the special committee appointed by it to carry out the work, Mr. Frederick Law Olmstead, the well-known landscape architect of Brookline, Mass., shows such a broad and reasonable view of the matter that we feel certain of good results from its endeavors.

In a general way the Association proposes to instruct country landowners, from whose trees, fences, outbuildings, etc., the irresponsible advertiser announces his wares, of the meaning of such trespass and how redress may be obtained. It further proposes to limit the extension of the practice as carried on under purchased consent of landowners, by bringing communities to regard such purchased consent as a stigma of sordid vulgarity on the part of the landowners.

Through direct legislation the Association is less confident of accomplishing its aims, and yet if sufficient sentiment can be aroused, it feels that the course might be brought to reflect this public sentiment in their rulings. The specific ground upon which legislative aid is to be expected must be that of a public nuisance, and the difficulty here encountered is in bringing the courts to rule that objects offensive to the sight are nuisances. But even with this difficulty before it the society does not despair, because, as Mr. Olmstead says in his report, "The question of what is a nuisance and what is not seems to be wholly a matter of degree and of judgment, the courts of to-day, we understand, classing as nuisances many practices to which earlier courts found no objection. Mr. Olmstead says further, "A city, let us say, has spent a million dollars, or two millions or five millions, as the case may be, in forming a great park with the main object of providing a region of quiet, rural, sylvan scenery, to which people can escape for rest from the worrying distractions and the ceaseless turmoil of city life. These millions are expended so that from the incessant calls upon the attention that set the strain of modern city life at so tense a pitch, there may be at least a temporary relief in the quiet enjoyment of simple, peaceful scenery that does not clamor even to be admired. But if in going to the park and returning home again the people must fight their whole way through busy city streets full of distracting movements, sights and noises, they reach home with nerves all set on edge again and much of the value of the park is wasted. It is, therefore, to conserve the full value of its investment in the park that the city undertakes the additional expense of a parkway which shall provide a main line of approach attractive in itself and free as far as possible from features irritating to the nerves. For this purpose land is taken and paid for; for this purpose additional sums are spent in construction and planting; and swarms of tired people seeking quiet and rest pass along the route thus prepared."

"Incidentally the adjacent land is given a frontage upon the parkway and made visible to those people. The landowners then erect signs constructed and painted with the most devilish ingenuity to catch the eye at every turn, to cry out as loud as color and form and size can be made to cry, 'Here we are! You can't get away from us! Look here! Look here! Look here!' Ugly and crude in the main, though sometimes not ill designed in themselves, these signs obtrude all sorts of sordid ideas upon the mind and will not let it rest. Distraction is their aim and

motive, the very reverse of the motive which was held to justify the rest of the parkway."

We believe that every physician who practises in a city is keenly alive to the immense therapeutic possibilities of the public parkways and can testify to the jangle produced in the nerves by the insinuating advertisements which abound therein. And there, as usual elsewhere, the medical variety is most obnoxious. Wherever the tired eye ranges it is met on every side by reminders of the mortality of the flesh, and before the rest-seeker has traversed a hundred yards of park road he learns from the most reliable sources—the advertisements—that he is the victim of at least six different diseases, all equally serious and all demanding the immediate use of as many different specifics. He learns that up to this moment he has been in error with regard to the clothes he should wear, the food he should eat, the bicycle he should ride, the house he should live in. He discovers furthermore that he has never really drunk a gentleman's whiskey, never smoked a gentleman's cigar. As a consequence his mind is filled with terror of latent diseases, and torn with remorse for a life barren of gentleman's whiskey and educational breakfast oats; and he slinks back wearily to the city with his intellectual faculties so paralyzed that he cannot decide whether salvation lies in the path of pleasant purgatives or three-dollar shoes.

Seriously, it behooves physicians and boards of health to cooperate with the American Park and Out-Door Association in its laudable undertaking to free communities from this rapidly-growing nuisance, the morbidly suggestive landscape advertisement; and we sincerely hope that the day is not far distant when nerve-racked people may obtain respite from their troubles in the quiet haunts of Nature without being harried into the belief that they are in need of perpetual purgation, ethylic nerve electrifiers and educational oats.

THE RADICAL CURE OF HERNIA.

Not many years ago any operation for the radical cure of hernia was regarded with suspicion by even leading surgeons. To-day it is considered by many to be a routine surgical procedure. The improvement in results has been due, not only to the improvement in surgical asepsis, but to the perseverance of certain persistent surgeons, who have improved the technic and evolved more correct theories.

While most persons dread a surgical operation, the promise of almost certain relief from the discomforts and insecurities of the truss holds out to them a much-wished-for deliverance from that disagreeable and uncomfortable piece of harness. A radical cure rarely—truss-makers say in 2 per cent.—follows the use of a truss, but only at the expense of long-continued discomfort. The majority of practitioners still advise their patients to get trusses and the results are often excellent. When the laity, on the other hand, order trusses themselves and put them on according to printed instructions they are often unnecessary and frequently do not fit. An ill-fitting truss does not properly hold up the hernia and it increases in size until some complication necessitates a hurried operation.

In an endeavor to present to conservative practitioners the advantages of the operation for radical cure over the treatment for relief by the truss, with the possibility of operation in extremity, J. Collins Warren (*Boston Medical and Surgical Journal*, Sept. 18, 1900) has discussed 98 cases of hernia operated on between the years 1888 and 1900 and has traced the degrees of greater success that has attended each step in improvement. These cases consist of 74 inguinal, 7 femoral, 12 umbilical, and 5 ventral hernias. The improvement in aseptic technic in later years is shown by the fact that since 1895 only 16 per cent. of the cases were septic, as compared with 48 per cent. prior to that date. The term "septic," as used by Warren, includes all cases which did not heal throughout by first intention, even those cases with the slightest stitch infection.

There are marked preferences among surgeons for different kinds of sutures in this operation. In two-thirds of Warren's cases silk sutures were used, sepsis following in only 17 per cent., while in 30 cases in which catgut was the suture material sepsis followed in 40 per cent.

The after-influence of sepsis is shown by the fact that relapses occurred five times as often after sepsis as after clean wounds, and that they followed the use of catgut sutures three times as often as when silk sutures were used. In 23 cases of inguinal hernia in which silk sutures were used no relapse followed, but one-third of the cases in which catgut was used suffered relapse. It would therefore seem that, as silk is easily sterilized, is stronger and more readily manipulated than catgut, it would be advisable to use it in preference. The opinion of Bull and

Coley, that silk is not as quickly absorbed as catgut, is not sustained by Warren who claims that it is quite as easily absorbed as chromicized catgut. The operation employed by Warren in the majority of cases was that of Bassini. Macewen's operation was used in a few of the earlier cases, but proved complicated and unsatisfactory.

The age at which operative treatment is most suitable is by no means agreed upon. There is always a good chance of a cure by the truss in children, but after twenty-one years the chances fall to 2 per cent. Bull and Coley give in a general way fifty years as the age limit for operative treatment for hernia, but Warren's hospital experience does not bear out this view. In a large number of cases operated on he found that nearly 20 per cent. were over fifty years of age and also that there were no recurrences reported among this number.

A hernia is generally conceded to be cured if there is no recurrence within a year after the operation. Warren was able to follow up 58 cases for a year or longer after the operation. Forty-five of these were inguinal hernias and a relapse was reported in 7 of them, giving 84 per cent. of cures. There was no recurrence in 3 cases of femoral hernia, or in 2 cases of ventral hernia, but in 8 cases of umbilical hernia there were three recurrences. A comparison of the number of cures obtained by operation on inguinal hernias prior to 1895 with the number obtained during the last five years shows a wonderful gain, due undoubtedly to improved technic.

As the operative treatment for the radical cure of hernia involves no mortality and is successful in 90 per cent. of the cases, it is to be hoped that practitioners in general will learn to appreciate it and employ it in all suitable cases. In childhood and youth, if the patient's parents are intelligent, the truss still has its place, but after the age of twenty operation should always be advised.

SALINE INFUSIONS IN PNEUMONIA.

The outlook in the treatment of pneumonia has not undergone much modification for a number of years. Statistical analysis when applied to the reports of different methods has shown that the kind of treatment has not materially altered the mortality. Indeed, it can be said that careful nursing without drugs gives as good results as any other plan of treatment.

It has come to be recognized, in a broad general way, that pneumonia patients may be grouped into three classes, *viz.:* (1) Infants, healthy young people and robust adults; (2) double pneumonia in old age, alcoholism, complicating constitutional disease, and (3) severe pneumonia in unhealthy or debilitated patients, usually over thirty. In the first group there is a marked tendency of the disease to run its course without fatal result if proper nursing is maintained; the second class of patients almost always die; but in the third group there are a number which give occasion for the most persistent and anxious watching, and it is in such patients that treatment methods, if of value, can demonstrate their usefulness.

Within recent times two procedures which demand attention have been advocated, the antipneumonic serum and the treatment by subcutaneous saline infusions. With reference to the former, we are not yet in a position to maintain that a specific has been found. Many different sera have been tried, but as yet our knowledge is too fragmentary to warrant conclusions. The method offers, however, much for future development.

The second method is not as new as many of its recent advocates would claim. Its action is based on the assumption of a bacterial toxemia and is simply a logical extension of the method by bleeding, and perhaps offers its best results in the combination of the two methods. Penrose of Baltimore in 1899 advocated the method quite strongly, and Wells before the American Medical Association in 1899 went so far as to say that by the combined method of venesection and venous saline infusions pneumonia could be made a curable disease. Recently (*British Medical Journal*, Sept. 29, 1900) W. Ewart and Beaumont Percival of London have tried simple saline infusion in a number of patients who seemed to offer but the faintest chances of recovery. The results were not very satisfactory, only one case in six recovering, but the general impression gained was that the method was of value and that it was not followed by unfavorable complications and delayed rather than aggravated the fatal results. "The instalment of relief which was observed in some of the cases reported suggests that in patients with anxious prognosis, but not actually of the worst type, this mode of treatment might be capable of making a favorable and perhaps a life-saving impression upon the attack."

ECHOES AND NEWS.

NEW YORK.

Dr. S. Purple.—The President and Fellows of the New York Academy of Medicine hereby express their high estimate of the character of the late Dr. Purple, as a citizen and a physician; their earnest appreciation of his valuable services as a Fellow and an officer of the Academy, and their grateful acknowledgment for rare books and pamphlets presented by him in large numbers to the Library of which he was the founder. They earnestly desire to extend to the members of his bereaved family their profoundest sympathy in this, the hour of their sad affliction.

Wm. H. Thomson, M.D., President.
Louis F. Bishop, M.D., Secretary.

Tuberculosis Hospital Site.—From the daily press we learn that the efforts of the residents of Clinton County to secure the location at Dannemora of the proposed hospital for the treatment of incipient tuberculosis, and their opposition to the site at Lake Clear selected by the Board of Trustees appointed by Gov. Roosevelt, have aroused the residents of this section of Essex County to vigorous protest. A committee of citizens has adopted resolutions which are to be forwarded to the State Board of Health and the Forest Preserve Board, by whom the selection of the site is to be made. The resolutions are as follows:

Whereas, Desperate attempts are being made by certain politicians to prove that the Board of Trustees appointed by Gov. Roosevelt to select a site for a hospital for consumptive patients has erred in its judgment in a selection of Lake Clear,

Resolved, That we endorse this selection and commend the good judgment of the Trustees.

Resolved, That we condemn as unbecoming good citizens the motives underlying the efforts of the opponents of this selection.

Resolved, That Dannemora should be used for the same purpose for which the State originally selected it—namely, for people who are to be confined and punished, and not for people who are seeking outdoor life and recuperation.

Resolved, That convict labor on buildings to be inhabited by the criminal class and inside the prison walls is proper, but that such convict labor should not be put in competition with the honest laboring man in the outside world.

Resolved, That the surroundings in this penal colony are incompatible with cheerfulness, but, on the other hand, would have a tendency to produce melancholia, a condition most to be avoided in tubercular patients.

Resolved, That a copy of these resolutions be forwarded to the State Board of Health and the Forest Preserve Board.

PHILADELPHIA.

Women's Homeopathic Hospital.—Dr. Mary Davis Ridgeway, for three years a member of the staff, has resigned in order to take a special course in surgery at Cornell University.

Hygienic Church.—The People's Church at Reading has begun the use of individual cups for communion service. The pastor is a pioneer in this line, having formerly introduced the custom in Baltimore.

Municipal Hospital.—The Board of Health has received a petition from the Women's Sanitary League asking that appropriate wards be fitted for the treatment of pay cases of scarlet fever and diphtheria. It is asked that the charges be made not more than $25 per week.

Evans Estate.—It is announced that the heirs and legatees have at last reached an agreement by which the estate will be settled in Philadelphia. As soon as the estate is turned into money the great dental institute will be begun.

State Hospital for Insane at Norristown.—The cost of maintaining the 2100 inmates during the past year was $3.29 each per week. The trustees have asked for one building for male consumptives, two for nurses and attendants, a pathological laboratory and a morgue.

Conservative Surgery.—Dr. B. F. Baer reports a unique case. The patient was a woman in whom tubal gestation was present. Abdominal section revealed a cystic condition of the opposite ovary which necessitated its removal. In order to save the pregnant tube the fimbriated extremity was dilated and by careful massage the contents of the tube were expressed. This maneuver was entirely successful and the patient made a good revovery.

Selling Literature Intended for the Sick.—An enterprising individual is turning a few pennies by soliciting magazines from people, under the representation of collecting them for hospital patients, and then disposing of them to dealers in second-hand books. This trick was exposed some two years ago. The perpetrator ceased his actions for a time, but has again begun his work.

St. Joseph's Hospital.—This hospital, which was formerly in some disrepute, is now making rapid progress. Abdominal operations were regarded as likely to be unsuccessful and ran down as low as two in one year. Last year there were more than 100 performed. A new departure has been made by allowing physicians to bring patients to the hospital and still retain full charge of the treatment. This is the only hospital in Philadelphia that affords such facilities.

Filthy Streets and Diphtheria.—An inspection of the streets in the sections of the city where diphtheria is most prevalent has shown some of them to be horribly filthy in spite of the efforts of the Board of Health to guard against such insanitary conditions. The paved streets are kept in good condition, but the unpaved streets and alleys are not. The Superintendent of Street Cleaning states that the latter do not come under his jurisdiction. The cases of diphtheria during the last week number 120. The total mortality of the city still continues unusually low.

Hospital Charity.—This question was under discussion at a recent meeting of the Medico-Legal Society. Efforts are to be made to secure legislation to district the city and place an overseer in charge of each district. Applicants for charity must then first apply to the overseer. This it is believed will lessen the abuse of promiscuous giving of charity by the various hospitals.

Mother's Congress.—The following resolutions were adopted at the recent meeting in Lancaster: (1) That we especially urge the women of our own State to work for the establishment of juvenile courts, for the complete separation of blameless from misdemeaning children, and for the care of all dependent children, as far as possible, in individual homes rather than in institutions. (2) Whereas, in Pennsylvania the women criminals are confined in jails and prisons, be it resolved that we urge the State Legislature to make an appropriation to establish a reformatory for women criminals similar to the one in Sherburne, Mass.

Bacillus Aerogenes Capsulatus.—An interesting case of known infection by this bacillus was recently treated at the Polyclinic Hospital by Dr. John B. Roberts. The patient was a girl who had sustained a compound fracture of the forearm, the skin opening being very small. In three days the forearm was gangrenous and multiple incisions were made with the hope of saving the arm. This was futile and the following day amputation at the middle of the arm was necessary. The flaps soon showed beginning gangrene, but this was finally checked and recovery followed. Examination at the Pepper Laboratory showed the presence of the bacillus aerogenes capsulatus which had invaded the blood-vessels as well as the tissues.

County Medical Society.—At the meeting of October 24th, Dr. A. H. Dare demonstrated a new hemoglobinometer. The instrument is adapted to the use of undiluted blood and has the following points in its favor: (1) The stratum of blood is always constant. (2) The possible error due to coloring introduced by diluting fluid is done away with. (3) The reading is made through a camera tube with achromatic lenses which magnify the color field about three times. A comparison with Oliver's method in a series of 500 cases shows an almost exact correspondence in the readings. Since blood-work is becoming of such importance the cost of this instrument, $15, makes it accessible to the general practitioner.

Dr. Henry W. Stelwagon gave a report of his visit to the Finsen Institute in Copenhagen where skin diseases are treated by concentrated light rays. Dr. Stelwagon will soon have a sun apparatus in operation at the Howard Hospital and later expects to have an electric appliance for the same purpose. The results will be awaited with interest.

Dr. Norman B. Gwyn of Batimore read a paper on the occurrence of typhoid bacilli in the urine and the means of disinfection. Recently experiments have been made with various disinfectants. Milk of lime scarcely deserves this name. The three most useful are bichloride of mercury, chlorinated lime, and liquid chlorides. Chlorinated lime is one of the most reliable, 30 cc. completely and almost immediately disinfecting 1200 cc. of urine. Two-tenths the volume of infected urine of one-to-one-thousand bichloride solution will thoroughly disinfect it in five minutes.

CHICAGO.

Medical Inspection of Public Schools.—At a meeting of the Physicians' Club, held October 29th, the following resolution was presented and adopted: Resolved, that it is the judgment of the Physicians' Club of Chicago that the results obtained by the medical inspection of the schools of Chicago demonstrate the high sanitary value of the system. As a life-saving measure it is of the greatest importance to the City of Chicago.

Visiting-Nurse Association of Chicago.—This Association was recently incorporated and a charter was applied for and granted. The object of the Association is to furnish trained nurses to those otherwise unable to secure skilled attendance in time of illness, to teach cleanliness and the proper care of the sick. At the end of the first year of the Association's work there were four nurses in its employ and 771 cases had been cared for. At this, the eleventh year of the Association's life, there are fourteen nurses and more than 500 cases a month are cared for. A corps of twenty untrained or emergency nurses, who work under the supervision of the doctor and visiting-nurse, has proved of untold value to hundreds of cases where the daily visit of the visiting-nurse is not sufficient for the proper care of the case.

Gift of Dr. Senn.—Dr. Nicholas Senn recently gave to Rush Medical College $50,000 which insures the beginning of a building project which will give the College the finest and best equipped structure for clinical work in the West. Architecturally the structure will follow the Italian Renaissance, the first few stories being of stone, and the four upper stories of terra-cotta and brick. The recitation room and the dispensaries will occupy the first, second and third stories. They will be equipped with all the latest improved medical and surgical appliances. On the fourth floor will be the laboratories. Their equipment will be the finest and most modern. The fourth floor will be connected with the Presbyterian Hospital Building by a covered bridge. Two amphitheaters for clinical work, capable of seating 150 students, will occupy the fifth floor.

Testing the Eyesight of School Children.—The fact that dulness of eye is closely related to dulness of mind has been conclusively shown by Professor Smedley, Supervisor of the Board of Education's Department of Child-Study. Among the deductions made by Professor Smedley from the

mass of statistics, as the result of examinations, are these: (1) Dull pupils have a greater number of eye defects than brighter pupils. (2) Defective eyesight causes dulness in the child. (3) The primary rooms in the public schools have the poorest light. (4) Boys have better sight than girls. (5) School-life is responsible for many eye defects. (6) The first three years of school-life increase eye defects one-third. (7) Of pupils whose sight is but one-tenth the keenness of normal, the number grows steadily larger from the beginning to the end of the school-life. (8) While in ordinary schools 32 per cent. had only two-thirds of ordinary keenness of sight, in one school 48 per cent. had that degree of eye defects. (9) Such defects undoubtedly were the cause of the presence of many of the pupils in that school. (10) Something must be done at once, at almost any cost, to save school children's eyes.

GENERAL.

Portrait of Dr. La Costa.—In response to the many requests for the portrait of the late Dr. J. M. Da Costa which appeared in the Medical News of September 15th, there have been prepared impressions, specially printed on heavy paper measuring eleven by fourteen inches, suitable for framing. These may be had at twenty-five cents each, by addressing a request to the Medical News.

Obituary.—Dr. Louis W. Read died at his home in Norristown, Pa., last week, aged seventy-two years. He was born in Montgomery County, Pa., in 1828 and graduated from the medical department of the University of Pennsylvania in 1849. When the Crimean War began he offered his services to the Russian Government, was accepted and served throughout the war, effecting important improvements in the treatment of gunshot wounds which were afterwards adopted in the United States and Europe. In 1861 he was appointed surgeon of the First Pennsylvania Reserves and later was made surgeon of United States Volunteers. In 1864 he took charge of the McKean Hospital in Baltimore where he served two years. He was surgeon-general of Pennsylvania and at the battle of Gettysburg removed a bullet from the body of Gen. Hancock after several other surgeons had failed.

War Against Osteopathy.—Swan L. Thompson, an osteopath, has just been fined $50 in the police court of Milwaukee, Wis., and ordered to pay the costs of his prosecutors, the Wisconsin State Board of Medical Examiners, for illegally using the title "doctor." The penalty is the same as that imposed in the cases of the Christian Scientists, who were convicted on the same charge. Mr. Thompson was accused in addition of illegally practising medicine without having a license, but this charge was abandoned by the prosecution under the spirited defense made to it. When the conviction was announced notice of appeal was at once filed and the osteopaths of the State, who are behind Mr. Thompson, say that it will be pressed. They assert that they have as much right to affix to their names the letters D. O., as Mr. Thompson did, as other persons have to use D. D. or LL. D., because they have studied at a college of osteopathy and are thoroughly versed in that system of treating disease. In the course of the prolonged hearing of the case several osteopaths went on the stand and explained the course of treatment they believe in. One of them on demand demonstrated with a skeleton that he had a scientific knowledge of the human body. The State Medical Board complained that pamphlets were illegally sent out by Mr. Thompson explaining osteopathy as a system of healing without drugs by using the bones as levers and so exciting the nerves as to cause the muscles to contract and produce a venous flow of blood to the heart. Osteopathists believe that disease is the effect of a local or general disturbance of blood and that a natural flow of blood is health. Counsel for Mr. Thompson contended that if osteopathic treatment was against the law it was illegal for trained nurses and Turkish bath attendants to treat sick persons. The osteopathists hope to secure a law which will put an osteopath on the State Board of Examiners and regulate their schools like other medical schools.

Training School for Nurses.—The United States Civil Service Commission announces that on November 20-21, 1900, an examination will be held in any city in the United States where it has a local board of examiners for the position of superintendent and trained nurse, Training School for Nurses, Freedmen's Hospital. The examination will consist of the subjects mentioned below which will be graded as follows:

1.	Essay (not less than 300 words)	12.5
2.	Anatomy and physiology	12.5
3.	Hygiene of hospital wards and sick-room	10.
4.	Routine requirements of hospital ward and sick-room	10.
5.	General nursing	10.
6.	Surgical nursing	12.5
7.	Obstetrical and gynecological nursing.	12.5
8.	Experience	20.
	Total	100

Applicants must be graduates of reputable training schools for nurses, and must have had at least three years' experience in hospital nursing. Age limit twenty years or over, but the Department desires that preference in certification be given to unmarried females between twenty-five and fifty years of age. From the eligibles resulting from this examination it is expected that certification will be made to the position of superintendent and head nurse, Training School for Nurses, Freedmen's Hospital, Washington, D. C., at a salary of $900 per annum, and to other similar vacancies as they shall occur. This examination is open to all citizens of the United States who comply with the requirements and

desire to enter the service. All such persons are invited to apply, and applicants will be examined, graded, and certified with entire impartiality and wholly without regard to any consideration save their ability as shown by the grade attained in the examination. Persons who desire to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application forms 304 and 375, which should be properly executed and promptly filed with the Commission.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, October 24, 1900.

CASE OF PLAGUE AT CARDIFF—THE GLASGOW PLAGUE OUTBREAK—REPORT OF PROF. ZABOLOTNY OF ST. PETERSBURG—PRECAUTIONS IN LONDON—THE RISK OF INFECTION FROM THE BOOKS OF PUBLIC LIBRARIES—OPENING OF NEW SCIENCE LABORATORIES AT KING'S COLLEGE—DISASTROUS EFFECTS OF THE WAR ON HOSPITAL FUNDS.

A FATAL case of plague has occurred at Cardiff on October 4th. The ship "Southgarth" arrived in the Tyne from the River Plate. One of the crew landed at South Shields, where he was taken ill on September 21st. He went to his home at Llandaff, where he arrived on the 27th. He was supposed at first to be suffering from typhoid fever, but plague was afterward suspected. Bacteriological examination of the blood and cultures from the bubo showed the presence of the bacillus pestis. He was removed to the Cardiff Fever Hospital in a dying condition. A nurse volunteered to take the case, and within twenty minutes of the man's arrival, he and the nurse and an attendant were completely isolated. He died on October 4th. The necropsy and inoculation of a guinea-pig confirmed the diagnosis. By consent of the widow his body was cremated. During a fortnight five ships have arrived at Cardiff from ports at which plague has been reported. Seven hundred rats have been destroyed, no less than 134 having been found on one ship. Their bodies were burned. The Local Government Board sent one of their inspectors, Dr. Buchanan, to Cardiff to investigate the arrangements made to check the spread of plague, and he has satisfactorily reported on them.

The outbreak of plague in Glasgow appears to have been completely checked. There are now 20 cases in hospital and it is twenty-six days since the last case was discovered. One more death has occurred. A most interesting report on the outbreak has been published by Prof. Zabolotny, of the Imperial Institute of Experimental Medicine of St. Petersburg, who has spent several weeks in Glasgow on behalf of his Government. In recent years he has been a member of the Russian Expedition for the study of plague in India, Arabia, China, and Eastern Mongolia. Before leaving Glasgow he drew up the following conclusions which he conveyed to the Medical Officer of Health: (1) The epidemic when compared with that of India, China, and Africa, and with those of Europe in recent years (Oporto, Kolobowka), is of the mildest description. (2) The extension is not great and the mortality is insignificant, which may be attributed to the energetic sanitary measures. (3) For the most part the cases are bubonic, which are epidemiologically less dangerous than the pneumonic cases. These latter are excessively contagious, because the sputum teems with plague bacilli. (4) As in the bubonic form contagion takes place only by contact with the skin, isolation and cleansing of linen play a most important *rôle* in prevention. (5) For persons in contact with the sick the best method of protection is the injection of 10 to 20 cc. of serum, as here practised. Treatment of patients is most effective with large intravenous injections (60 to 120 cc.). (7) The necropsies of fatal cases show a picture of protracted illness (suppuration nodules, mixed infection), and not that of an acute malady terminating fatally in from two to three days.

Should an outbreak of plague take place in London it is proposed to admit patients to the fever hospitals of the Metropolitan Asylums Board. But the *British Medical Journal* doubts very much whether these hospitals could supply the accommodation, for cases of scarlatina and diphtheria are constantly refused admission owing to lack of accommodation. The *Journal* thinks that temporary wooden hospitals, which could be destroyed by burning, should be constructed. Again, how about nurses? No doubt many heroic women could be found; but the question of infection is a serious one. Out of a staff of six nurses in Hong-Kong two contracted the disease and died. As a precautionary measure it is thought that nurses should be asked to volunteer at once to be injected with Haffkine's prophylactic serum. It will not do to wait until they are called upon to nurse plague patients.

A paper by Mr. MacAlister, Librarian of the Royal Medico-Chirurgical, and Dr. W. G. Savage, Bacteriologist to the Cardiff Public Health Laboratory, dealing with an "Investigation into the Amount of Risk of Contracting Infectious Diseases by the Use of Public Library Books," read at the annual meeting of the Library Association at Bristol, is of great practical importance. From time to time the public are frightened by the suggestion that during epidemics the books of public libraries are a grave source of infection. But the authorities generally believe that if reasonable precautions are taken by notification and withdrawal of infected books there is practically no danger. The authors of this paper hold that there is no ground for drastic measures, and that there would be more justification for stopping all

public conveyances and prohibiting all social gatherings during an epidemic than for closing the public library. For the purposes of investigation soiled library books and new books were used for weeks by patients suffering from diphtheria, typhoid fever, and tuberculosis, and then subjected to bacteriological examination. The result was that it appeared impossible for infection to be conveyed by means of books. But there was one exception: By wetting the thumb and turning over the leaves of an infected book it was found possible to convey germs to the mouth.

New science laboratories will be formally opened at King's College, London, on October 30th, by Lord Lister. The Lord Mayor and sheriffs will take part in the ceremony, and a great number of invitations have been issued to representatives of learned societies, medical schools, etc. The structural alterations required and the new equipments have cost $100,000, which has been in part generously subscribed by the public in spite of the demands for the various war funds. The College will now have laboratories for physiology, bacteriology, biology, botany and geology which can compete with the best continental ones. The bacteriological department, which has been the most complete attached to any medical school in England, has been greatly enlarged. There will be a technical laboratory, a new class-room, a research-room, and a bacteriological library.

The Boer war has had widespread commercial effects. It has affected the prices of everything from a cup of coffee to a scrubbing-brush, and from a pair of boots to a football. A very serious consequence is the influence on hospital finances, which in one or two cases has been almost disastrous. The following decreases in the revenues have occurred: St. Thomas's, £7500; King's College, £2900; Orthopædic, £1000; Cancer, £4928; Great Northern, £2076. In the case of a few small institutions insignificant increases (from other causes) have occurred. From 39 out of 87 different medical institutions to which a note of inquiry was addressed a reply has been received. These 39 report a total loss of £20,000. The extraordinary amount subscribed by the public to various war funds has diverted the stream of charity.

NORMAL AND PATHOLOGICAL BILE SECRETION—UNUSUAL SEQUELAE OF GONORRHEA—CEREBRAL INFLAMMATION—APPENDICITIS LARVATA—NEW APPARATUS FOR BLOOD TRANSFUSION—POST-OPERATIVE ILEUS—RUPTURE OF THE UTERUS—DURATION OF GESTATION—MARTIN'S TREATMENT OF THE UMBILICAL CORD.

Brauer (Heidelberg) at the Seventy-second Assembly of the Deutscher Naturf. u. Aerzte in Aachen, September 16 to 22, 1900, rehearsed his conclusions upon the normal and pathological composition of freshly-secreted bile in order to establish some relation between it and disease. Hitherto such work has been confined to the autopsy-table and on this account is certainly too untrustworthy to be of scientific interest. Of more recent years advance in diagnosis and in surgical technic has led to more and more frequent operation for gall-bladder disease with the common establishment of fistulæ from which most of his human specimens have been gathered. The other and wider source of bile were animals in which fistulæ, various diseases and drug intoxications were produced. The chief point investigated was the influence of bile acids on the total production of bile. His results indicate that after a definitely long persistence of a fistula the total output of the bile and of the biliary acids sinks to a definite level. The loss in the acids of the bile must be renewed through the food if the secretion is to remain at its normal state, because the liver needs a definite quantity in order to produce bile in sufficiency and health. Again the nutritive influence of the bile upon the other glands of the body is very similar to it upon the liver itself, and this seems to account for the failure of gland function and of general nutrition seen in animals with fistula. Hence is the importance of determining the actual quantity of bile as an index of the real liver activity. The next field surveyed is that of pathological bile. In health not even traces of sugar were found, even when four per cent. of it appeared in the urine of alimentary glycosuria none could be detected in the gall. But on the other hand one dog having pancreas diabetes developed in three or four days 5 6/10 per cent. glycosuria and 1 2/10 per cent. sugar in the bile and a second dog showed 3 6/10 per cent. and 8/10 of 1 per cent. respectively in each. Whether in this disease hyperglykemia is produced or whether through changes in blood-pressure or through the too rapid conversion of the glycogen sets up glycocholia has still to be decided. Interesting results followed deep intoxication with ethyl and amyl alcohol. Distinct albuminocholia was found disappearing in about three days, more pronounced in degree with amyl alcohol. Epithelial casts were present, many of them dichotomously arranged. With exhibition of potassium iodide cylindroids, much longer, contorted spirally, appeared. Further many cells very like hepatic parenchyma cells were found. These circumstances support the theory of Aufrecht that in cirrhosis of alcoholic origin the parenchyma is first affected.

Eulenburg (Berlin) said the gonococcus is known to be the cause of remote sequelæ. Arthritis, endocarditis, pelveo-peritonitis, neuroses, neurasthenia, chorea, sterility and impotence are the diverse possibilities of this germ. He has observed lately distinctly localized nerve lesions and has differentiated neuralgia, neuritis with paralysis and muscle atrophy and paralysis and myelitis, including fourteen instances of neural-

gia, four of muscle atrophy with paresis and one of myelitis. Neuralgia attacked the nervus ischiadicus, tibialis, radialis and ulnaris. In the first named, associated nerves like the femoral, obturator and genitocrural were often involved. All the patients were young and all the neuralgia began between the second and seventh months after the original infection. Muscular atrophy appeared in the neighborhood of joints affected by the disease, and were it not for the ascertained cause would have made one think of juvenile atrophy. One case of myelitis with endocarditis and arthritis resembled tabes dorsalis in its other symptoms, absence of patellar reflexes and great pains in the lower extremities. Cure followed three years of treatment. The diagnosis rests upon the presence of the germ; in absence of that, upon a careful history of an attack and the results of a thorough physical examination. Iodipin is of therapeutic value in the treatment.

R. Lenzmann (Duisburg) reported a few additional cases of what Ewald has termed *appendicitis larvata,* characterized by variable attacks of dull pain about the gastric and umbilical regions, nausea, vomiting, diarrhea, little or no pain or tenderness about the region of the disease, but a readily and distinctly palpable appendix. The diagnosis was cleared in each case by the operation and the lesions were in each infiltration of the whole parieties, ulcers of the mucosa and adhesions. The explanation of the referred pains seems to be the anastomosis of the inferior mesenteric plexus with the solar plexus by means of the gastric nerve.

M. Dinkler (Aachen) in the light of four recent cases in his practice described the effects of inflammation in the cerebrum among children. He exhibited a case of right posthemiplegic athetosis with a history of diphtheria, then encephalitis with hemiplegia and finally athetosis. Tendon transplantation was the suggested treatment. The brain of a hemiplegic child was shown in which the cause of disease appeared to be a very large posthemorrhagic cyst.

Weintraud (Wiesbaden) exhibited the apparatus for blood transfusion, having simplicity, practicability, painlessness and asepsis in its favor. When the veins of the upper arm are subjected to elastic ligature the pressure rises to 75 to 85 mm. of mercury and equals about 1 m. of water-pressure. This fact is taken advantage of in the simple device which consists of two small cannulæ inserted each into the vein of the patient and the blood-giver. With the latter the sterile rubber tube, with connections at the ends, is attached and, after blood flows freely from it, is connected with the patient's cannula. In from 5 to 10 minutes, through fine tubes, 150 to 250 c.c. of blood will pass. If salt solution also is desired a T-tube with a vertical arm, a meter long, dipping into the solution, may be inserted in the course of the rubber tube.

Winternitz (Tübingen) considers embolism of the lungs and ileus two unfavorable factors in any operation which are entirely beyond the surgeon's responsibility. Ileus may be septic, after a septic peritonitis, mechanical without sepsis after occlusion by adhesious kinks or twists, paralytic by nervous action or by inexplicable cause as occurs often after total extirpation of the uterus. He reported eleven cases of post-operative ileus, 5 after total vaginal hysterectomy, 3 being septic, 7 mechanic without sepsis, and 1 paralytic, observed among 459 laparotomies, 280 vaginal hysterectomies and 98 colpoceliotomies, a total of 837 cases. The septic cases were not saved by a second operation, but 6 of the mechanical cases were. He holds that by careful observation of the symptoms and physical signs from the first day of the operation it is possible to differentiate the septic from the purely mechanical varieties. Peritonitis presents early invasion, commonly fever, uniform meteorism, universal tenderness. Mechanical ileus has delayed invasion, rarely fever, always elevation of pulse, commonly localized meteorism and tenderness, visible and palpable movements of the gut at some point which are accompanied by acute pain and increased tenderness. Under these signs a second operation should always be done. As to the time when such should be undertaken he laid down the following rules. If no flatus is passed and the earliest symptoms of ileus appear, consisting of singultus, vomiting, especially of green fecal matter, massage and lavage are resorted to. If these symptoms continue and in addition meteorism, fall of temperature and rise of pulse-rate ensue, a secondary operation should at once be done on the diagnosis of mechanical ileus. The further salient points of the subject were enumerated as follows: First, in purely mechanical ileus due to vaginal operation treatment must be undertaken through the original route, later in the face of failure, laparotomy must be done. Second, original laparotomy wounds must be opened, adhesions freed and then the obstructed gut emptied entirely of its contents by incisions at various points through which it is stripped clean. These openings must be carefully sewn and the toilette of the peritoneum rigid. Gloves are in these cases recommended. Third, these procedures are useful also in paralytic ileus and should be followed in promising cases. In true septic cases the frequency of failure almost contraindicates interference.

Franz (Halle) reviewed twelve examples of uterine rupture, ten of them complete. The signs of the approach of this calamity are not always definite. In only one of his four patients were there indications of undue tension and stretching. Even the actual presence of a rupture may have very few manifestations The causes of death are bleeding and infection. So frequently are they infected that it would be well to treat all on that basis and to resort to the radical operation. The vaginal route for extirpation is the best. If radical ablation is refused, then a purely expectant plan should be first tried.

Von Winckel (Munich) presented a tabulated report on the duration of gestation. He as-

sumed the premise that the weight of the child bears direct relation to the length of the pregnancy. His observations include only children weighing four kilos or more. In 1007 instances he elicited as accurately as possible from the parents the date of the last menstruation and the most likely date of the conception. The lowest level appeared as 280 days after the first well day following the last menstruation or 275 days after the probable conception, the highest level included 321 and 336 days. He now subdivided his series into groups according to 10 days, namely, 280 to 290 days, 290 to 300 days, and so on. In this manner he discovered 31 examples of very long gestation, one well over 310 days. From these facts he asserts that in legitimizing offspring a pregnancy of 310 days should be acknowledged by law.

Wirtz (Köln) presented the results of 150 cases of treatment of the navel in the newly-born by the method of Martin, namely, ligation with silk close to the navel and burning down to it with the actual cautery. This procedure has the advantages of securing more rapid falling-off of the stump, more prompt and smoother healing of the core, simplicity of management, and decreased danger of infection. Putrescence of the navel-wound, through absorption in the excoriations caused by the silk against the tender skin of foul bath-water, was not observed. Hematomata following cutting in of the silk has also not occurred. As the scab-tissue in the core from the burn possesses certain affinity for moisture, he suggests a wet dressing of alcohol which will both sterilize, dry and harden.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, Held October 2, 1900.

J. Arthur Booth, M.D., Chairman *pro tem.*

Periodical Psychoses.—Dr. A. B. Defendorf read this paper. He said that years ago all forms of insanity were looked upon as more or less periodical, but gradually this list has been reduced to periodical mania and periodical melancholia. The English and American observers have been slow to recognize periodical insanity. The record of hospitals for the insane show it to constitute a not inconsiderable percentage of cases admitted, coming second to dementia precox. These cases are characterized by intense psychomotor restlessness, exhibiting no signs of fatigue after weeks or months of excessive motion, and by unclouded consciousness, except in the extreme maniacal condition called delirious mania. These patients are rich in words if not in ideas. Delusions, when present, are transitory and are usually of the expansive type. The patients are happy and contented, yet they change very suddenly from happiness to melancholia or *vice versa*. In the depressive form, the associations of ideas show retardation, and the emotional attitude is uniformly one of depression or despair. More or less stable delusions are present. Cases are found showing both the maniacal and depressive elements, but usually one or the other predominates. The most prominent etiological factor is defective heredity, found in from 70 to 80 per cent. Other causes are shock, acute diseases and mental strain. When the first attack occurs after childbirth it is apt to recur with each succeeding confinement and continue after the climacteric. The first attack is apt to be of the depressive form. More than half of the cases occur before the age of twenty-five. As the attacks are repeated, the lucid intervals, during which the mental faculties are fully retained, tend to shorten. The prognosis of the psychoses is bad. During the height of the disease, or in the extremely maniacal or depressive forms, death may occur from exhaustion, or may be self-inflicted. The author's conclusions were: (1) Periodical insanity is characterized by a definite symptomatology, which permits of differentiation in the first attack; it is a prominent psychosis.

Dr. B. Sachs said that although all recognized the existence of such a thing as periodical insanity, danger lurks in the term because almost all forms of mental phenomena are apt to exhibit a tendency to recurrence. For this reason a regular recurrence of, for instance, mania and depression, with perhaps a lucid interval, should be insisted upon. It was rather curious that those describing periodical insanity insist that there must be marked depression. He could recall a case of distinct hypochondriasis followed by a lucid interval of seven years and then an attack of pronounced melancholia. There was again a lucid interval followed by an attack of mania. Attention was called to the remarkable suddenness with which the patient passes from one state to another. He had had under observation a girl who had been in a state of depression for over eight months, and then very suddenly had had a lucid interval lasting one year. This had in turn been followed by acute mania.

Dr. W. D. Granger said that a few cases of undoubted circular insanity were so decided in their symptoms that they could not be mistaken for anything else. This was particularly true if the person was seen late in life, and had a history of recurrent attacks extending over many years. There were, however, many cases less pronounced in type, rendering it difficult to classify them. He had personally seen only a few cases of circular insanity. He had never seen the sudden changes referred to by the last speaker, nor had he ever seen a case of true incoherence in connection with circular insanity. He had seen several cases of recurrent insanity in which there were from two to five attacks of rather mild melancholia. He had had under his care a young woman suffering from this form of insanity, and also her mother, brother and sister. The sister had a most violent mania, proved at

autopsy to have been a complication of typhoid fever. She had also periodical attacks of active though not violent mania. Another form of the circular type that he had noticed and had never seen described in the text-books was the form of chronic mania developing, in the last few years of life, recurrent attacks of mania and melancholia.

Dr. William H. Thomson said that he had had under his continuous observation for ten years a case of periodical insanity—probably the only one to which he would be willing to apply the term. The attacks had recurred regularly every other day all these years. The patient was a man, forty-eight years of age when the disease had first set in. There was no hereditary psychosis. At the beginning he had been attacked with melancholia and had attempted suicide. Attention had been early directed to the fact that his condition was worse every other day, and for this reason he had had most thorough and persistent antimalarial treatment. When first seen by the speaker, his memory had been good, and he had been in no way irrational. The temperature had been normal. The next day his temperature had risen to 101° F. and he had become delirious. On the following day his condition was that noted at the first visit. The febrile symptoms ceased after about three months, but in other respects the case had kept up this alternation ever since that time. Examination of his secretions had thrown no light whatever on the etiology of his singular mental disturbance. The type was that of melancholia with excitement. He had never been truly maniacal. Regarding periodical psychoses in general, Dr. Thomson said he could not agree with the reader of the paper that they constituted such a definite class, for, if so, they should be definitely periodical. Another case was then cited in which the attacks had begun with talkativeness and an appearance of well-being, which commonly lasted for about six weeks, and were then followed by extreme mental depression. At no time was there any confusion of personality or any delusions. The attacks of mental paresis lasted two or three months, and usually came on every winter. Such a case seemed to him a true example of periodical psychosis, but many of those described in the paper seemed to him to come rather under the head of relapsing than periodical insanity.

Dr. William M. Leszynsky said that no one could tell at the first attack whether there would be recurrence or not. With a good previous history it was an entirely different matter.

Dr. L. Pierce Clark said that while in a hospital for insane he had seen a case of intermittent mental stupor which recurred at short and fairly regular intervals, thus resembling in some respects the case reported by Dr. Thomson. Such cases were very rare, only six being on record. Sudden transitions were quite characteristic in the mental disorder first described by Charcot in connection with mental epilepsy.

Dr. Defendorf said that the periodicity, and that an irregular periodicity, is the characteristic of the whole course of the disease throughout the life of the individual. But there are certain fundamental symptoms, such as the condition of the memory, the tendency toward deterioration, and the character of the delusions and hallucinations upon which the diagnosis should be founded. Relative to the sudden transitions from one state to another, he said that this occasionally happens over night.

Status Epilepticus: Its Nature and Pathology.—Drs. L. P. Clark and T. P. Prout presented this paper, Dr. Clark reading the clinical portion. About forty-five cases formed the basis of the paper. Unfortunately only five cases could be studied histo-pathologically. The modern notion of status is that it is the acme or true climax of the disease, and not, as formerly supposed, a chance termination of epilepsy that by proper treatment could have been avoided. It is a state of epilepsy in which one seizure follows another so closely that the previous psychical exhaustion is not recovered from. One case at the Craig Colony for Epileptics had 384 typical psychic seizures in one day. It occurs with about equal frequency in all the different forms of epilepsy except that dependent upon organic brain disease. The latter constitute one-half of all the cases of status. Exhaustion paralysis is very characteristic of status. No foundation had been found for the statements of some writers that either age or sex exerts any influence. According to their experience, the shortest intervals had been in those developing their epilepsy between the age of ten and sixteen years. On an average, eleven years elapse between the beginning of the epilepsy and the occurrence of status. Menstruation in women does not seem to be productive of status. In the great majority of cases the approach of status is denoted by a steady increase in the frequency of the epileptic seizures. They had seen 300 attacks a day in several cases, and still recovery had occurred. One case had had status epilepticus for twelve days, and had recovered, having had during this time 1800 seizures. The temperature elevation in status usually begins after the first severe convulsion, and there is usually a direct ratio between the number and severity of the convulsions and the elevation of temperature. The record of the pulse, temperature and respiration frequency gives the best indication of the severity of the status. Generally the maximum of the fever marks the maximum of the seizures, and if the fever persists after this one should be led to suspect some complication. Occasionally the fever subsides by crisis. Occasionally also the temperature rises to 107° or 108° F. As to the cause of the fever curve, he said that some look upon the elevation of temperature as purely psychical, while others believe it is the result of a direct effect on the heat center. The pulse-rate increases in frequency with each attack, but the pulse curve

usually runs nearly parallel to the temperature curve, though responding more slowly on recovery from status. Almost always there is Cheyne-Stokes respiration, but it is not so unfavorable a symptom as in some other disorders. Both pneumonia and pleurisy are fairly frequent complications. The prognosis of status is necessarily grave. A low temperature is supposed to be a fair sign, though there may be recovery after a temperature of 107.5° F. Paralysis of the muscles of deglutition is a very unfavorable sign. The gradual, steady increase in the symptoms is the most unfavorable sign of all. Many patients have a record of two to five status periods, and it is probable that the mortality does not exceed 25 per cent. It is possible to abort a case of status if taken in time, and certainly the present mortality should be reduced. The plan of treatment pursued in the cases mentioned in the paper was as follows: At the outset, the patient was given a dose composed of 25 grains of bromide, 20 grains of chloral and a large dose of opium and morphine. If the convulsions are not controlled, thirty or forty grains of chloral are given by the rectum, and if this is not sufficient, bromide is given hypodermically in a part of the body that will be the least painful if abscesses form, as they often do after such injections. The latter are very painful and should only be given in the stuporous stage. They usually control the condition.

Dr. Prout then took up the pathological side of the subject. He said that the modern belief was that the epileptic storm has its seat in the cortex. Recent experimental research seemed to warrant the following conclusions: (1) That the transmission of the impulse in epilepsy is through the extrapyramidal tracts which transmit motor reflex impulses; (2) that the sensory portions must be irritated in order to produce the fit, and (3) that the fit appears to be a complex reflex phenomenon. The paper was founded on a study of 13 cases. In all but two the post-mortem examination was made within seven hours after death. The changes found in the brain are by far the most pronounced in the status cases. The degree of chromatolysis seems to depend upon the number and severity of the convulsions. In the cells of the second layer the nucleus is swollen markedly; the nuclear membrane is hazy and indistinct, and the nucleolus is frequently replaced by a granular mass. These are especially numerous in the status cases. Many nucleoli were found far removed from the cells to which they belonged. He had examined the normal human brain with regard to this nucleolar extrusion, and had found it comparatively infrequent. Leucocytes clinging to degenerated nerve-cells were also very frequently observed. The neuroglia were studied in seven cases, and the conditions found to vary a good deal. A broadening of the outer cortical layer was fairly constant, and occurred apparently at the expense of the cortical layer. The condition of the neuroglia seemed to depend largely upon the condition of the epilepsy. It was more pronounced in the insane epileptic than in cases of simple epilepsy. When morbid processes attack the nucleus, the vitality of the cell itself is endangered. The increase in the neuroglia is the result of nerve-cell destruction. The author's conclusions were: (1) It would seem that epilepsy is essentially a sensory phenomenon; (2) the essential lesion pertains to the nucleus of the cortical cells and jeopardizes the cell; (3) the chromatolysis is probably a nutritional change brought about by the jeopardization of the nucleus; (4) the rôle of the leucocyte in the cortex after severe convulsions is most probably that of the phagocyte; (5) the neuroglia proliferation in epilepsy is one of the more remote consequences, and (6) epilepsy is a progressive disease of which status is the climax.

Dr. Schlapp said that he had had occasion to treat two cases of status during the past summer, and both had recovered. One case had had thirty attacks in eight hours. She had then become stupid and had finally developed hallucinations, the whole condition lasting two weeks. In both of the cases there was such a large quantity of albumin in the urine that the latter became solid on boiling. He thought this condition was commonly present in status. He did not think it right to assume that the second or third layer of cells could be taken as sensory cells, so much depended upon the particular region of the brain. Most of these cells were now looked upon, in opposition to the theory of Bruce, as associated cells.

Dr. Defendorf asked regarding the temperature of the case dying of status. He had had an opportunity of studying two cases, and in both there had been what had been called "acute alteration." This was often found in other conditions, particularly where there had been high temperature.

Dr. Sachs asked whether in these cases of status epilepticus gross changes had been found that might, in some way, have accounted for these cell changes. A number of years ago he had examined the brain of a child dying in status, and the one condition found at that time had been a very large subpial hemorrhage covering almost the entire brain. He would like to know whether in the brains examined by Dr. Prout similar conditions had been found. If they had, it did not seem to him fair to determine the true pathology of epilepsy from patients who have died in status. A truer knowledge of this pathology should be obtained from a study of the brains that had not undergone such secondary changes. The plates exhibited showed cellular changes such as had been reported in a number of very widely different diseases of the brain.

Dr. Schlapp said that he had seen recently a case presenting hemorrhages throughout the membranes.

Dr. Leszynsky said that fifteen years or more

ago he had published a paper entitled "Epilepsy as a Cause of Death." In every one of the cases coming to autopsy there had been intense venous stasis, and in some a few small hemorrhages. One or two of these patients died within two hours, and one after a single convulsion. A very competent pathologist had made the autopsies. At that time the most successful method of treatment of these cases had been early venesection, and he had seen no reason to change his view regarding the efficacy of this treatment. The injection of chloral into the rectum was certainly very satisfactory. He had practised venesection because of the intense venous stasis, not only found at autopsy but seen in the face of the patient.

Dr. L. P. Clark said that albuminuria had been frequently observed in the cases that they had studied, yet the quantity had varied greatly, and had not been at all in proportion to the severity of the seizures. In most of their cases there had been no systematized delusions present, and the delirium had resembled that of typhoid. A very large number of gross lesions had been found as the result of the severity of the convulsions. He had seen intense venous engorgement and hemorrhages, although sometimes these had been absent in very severe cases of status.

Dr. Prout, in closing, said he did not wish to be understood as saying that the invasion of the cortex with leucocytes is characteristic of epilepsy. It is well known that such an invasion is marked in general paresis. He had only mentioned the fact as showing that the leucocyte was carrying off effete material. In speaking of the cells of the second layer, he had referred to them as sensory in contradistinction to those which we are accustomed to associate with motor phenomena. He did not think it had been conclusively shown that these cells are associational in character. Many of the sections figured in the plates show the presence of punctate hemorrhages.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 18, 1900.

The President, Wm. H. Thomson, M.D., in the Chair.

Symposium on Infant Feeding.

Advantages of Sterilized Milk.—Dr. A. D. Blackader of Montreal opened the discussion. He said that the gastric digestion of infants is imperfect in that microbes which find their way into the digestive tract are not as readily destroyed and thus rendered harmless as in the adult. This barrier to the entrance of bacteria into the system not being present, sterilization of the food material supplied becomes absolutely necessary. Cow's milk is never sterile, even under the most favorable circumstances. If it is obtained from the cow with as great attention to cleanliness as possible and then immediately put on ice and kept at a low temperature until used, very few bacteria will be found in it. If these precautions are not taken, it may easily swarm with germs of various kinds. Some method of removing the bacteria is absolutely necessary. Pasteurization kills 99.8 per cent. of the microbes in full milk. It has been said that cream is more resistant to Pasteurization. Microbes that escape destruction are all of them sporebearers. The older the milk the more difficult it is to Pasteurize it.

Preservation of Milk.—Pasteurized milk will remain unchanged for a considerable length of time, especially if it is kept at a temperature just above 0° C. If it is not kept at this low temperature, however, fermentations are set up and these disturb infantile digestion. This liability to fermentation also occurs even in sterilized milk that has been heated up to 100° F. While Pasteurization is quite as effective as sterilization, it has no more advantages than the other process.

Bacterial Destruction.—All the now known pathogenic bacteria succumb to Pasteurization. The bacillus of yellow fever, of typhoid fever and of diphtheria have been shown by a number of experiments to be destroyed. Tubercle bacillus was thought to be more resistant, but Smith showed that the bacilli of bovine tuberculosis are destroyed at 140° F. if proper precautions are taken. The pellicle which forms over milk protects them so that this must be removed or the milk stirred during the heating process.

Changes Due to Heat.—When milk is heated certain changes which interfere with its digestibility take place. It is possible also that unheated milk may contain ferments which are an aid to digestion. In fresh milk the presence of a trypsin has been noted which is destroyed by heating. In recent years it has been found that immunity to disease in animals is not conferred upon their young by direct heredity. If the young animals are suckled by a mother who is immune to disease they acquire that immunity. The substances in the milk which confer this immunity, however, are destroyed by a heat of 60° C. These disadvantages of heating milk are now well recognized. It is necessary to choose between the two evils of a milk containing germs and one the digestibility of which has been impaired. It would seem, however, that the evils consequent upon Pasteurization are much less than those due to sterilization at a high temperature and that practically none of the pathogenic bacilli are left alive. The changes induced in the milk by Pasteurization are not very great.

Scurvy and Artificial Feeding.—Dr. J. P. Crozer Griffith of Philadelphia said that the American Pediatric Association had collected 379 cases of scurvy. As a member of the committee who made the report the present occasion seems a suitable one to discuss some of the features of that investigation. In 356 of the cases reported the diet of the children at the time the disease de-

veloped was given. Two hundred and fourteen of them were being fed on some proprietary food. In some cases sterile milk was used in addition to the food. In 44 of the cases some form of malted milk was employed. In 34 of the cases some brand of condensed milk was employed. In the others various of the well-known advertised foods were used. Fifty or 60 cases developed in those that were using a preparation containing insoluble starch. Altogether over 200 of the cases were receiving starch in some form in their diet. It is to be noted that this is 56 per cent. of the whole number of cases. Suspicion was aroused that the cause of scurvy was in most cases cooked or partially-cooked food which the infant's digestive organs were unable to assimilate. Several of the children, however, who developed scurvy were being fed on raw milk, while ten of them were fed exclusively on breast-milk.

Cure of the Scurvy.—The method of treatment employed for the cure of the disease was different in different cases. In only three was fruit-juice alone employed in addition to the diet which they had been given before. In 260 cases fruit-juice or meat-juice, together with a change in the diet, was employed. In 58 cases change of diet alone sufficed. Of these, in 24 cases, proprietary food was abandoned. In 20 of them the use of sterilized milk was abandoned. In the remaining 14 a cure followed the abandonment of starch in the diet. Two of the cases were cured by being taken from the breast and put on artificial food.

Interesting Scurvy Cases.—Dr. Griffith gave the details of some cases of scurvy in his own practice. In one family a pair of twins developed suspicious signs on the gums on the same day. These were neglected and a few days later the scorbutic hemorrhages and the painful joints developed on the same day in both children. Their symptoms yielded in a corresponding way to treatment and recovery was complete at the same time. In the treatment of scurvy it is probable that fruit-juice alone in addition to the ordinary diet will cure most cases. It does not seem probable that the scurvy is due to changes in the food produced by heat. Even if it were so it will be necessary to choose the lesser of two evils. Many infants will be protected from serious digestive troubles because of the heating of milk. A few of them will be exposed to an easily curable disease. It must be remembered that individual susceptibility plays an important rôle in the etiology of scurvy. Of two children fed on exactly the same material, one will develop scurvy, the other not. Any serious objection to continuance of sterilization can scarcely be urged from the present status of knowledge as to the connection between infant feeding and scurvy.

Pediatries in Europe.—Dr. T. M. Rotch of Boston said that the discussion evoked by Jacobi's paper at the Paris International Medical Congress showed that Europeans fail utterly to appreciate what America has done in a scientific way for the advance of our knowledge of infant feeding. Monti, to whom many Americans looked as a suggestive professor in the old days, seems unconscious of the work that has been done by his students, sometimes as the result of his inspiration. It is not surprising that Europeans should neglect the work done in America in other lines of medical research, though that is one of the most disappointing features of many a European medical discussion. But that they should utterly neglect the advances made all along the line in pediatrics in America seems altogether unwarranted.

The Use of Cereals.—Cereals are added to milk for infant feeding supposably for two reasons—first, because of their actual nutritional value; second, because they act as digestants. The nutritional value of cereals added to infant's food is extremely problematic. Starch is probably indigestible for the infant, and even if digested its nutritional value is not as great as that of milk. There seems to be very little difference in the value of the various cereals that have been employed. Barley-water has been especially lauded by some; Heubner declares his preference for rice; others have suggested the use of other cereal solutions as diluents. White in a series of experimental researches showed that barley-water when employed as a diluent produced a finer coagulum, but when barley-water plus lime-water was used as a diluent, the coagulum was still finer. A great deal depends, however, on the constitution of the milk, especially with reference to its albuminous constituents. Where the caseinogen is in excess the coagulum will be tough and coarse no matter what the diluent. Where it is lessened in amount simple dilution will produce a fine clot. It would seem, therefore, that the addition of cereal to milk for infant feeding is not needed and that its use is irrational and unnatural.

Emulsions.—The making of milk emulsions for infant feeding has attracted considerable attention of late years. The practical purpose is to obtain a food by separating the cream from the rest of the milk, and then adding to the watery part as much of the separated cream and other ingredients as may be necessary to produce a food having such a composition as will be best adapted for a particular infant. As a diluent for the fluid contents of the milk, lime-water in various proportions seems to be the best agent. When milk is Pasteurized a finer coagulum is produced than when it is left untreated, so that it is the Pasteurized milk which is used as the basis of the emulsion. It has been said that the separation of the cream from the fluid milk injures the nutritional value of the milk. Especially has it been urged that when the cream is separated by a centrifugal machine, a proper union of the cream and watery solution cannot be hoped for. As a matter of fact, the amount of cream obtained from milk by the ordinary gravity process and by the centrifugal separator is exactly the same.

In a series of observations made in this matter in Boston, 16 per cent. was the average amount of gravity cream as well as of centrifugal cream. As a rule, the objections to the use of emulsions for baby feeding come from those who have had least experience with them.

Proteids of Milk.—The estimation of the lactalbumen of milk does not give the total proteids. The amount of the two principal elements which enter into the proteids, namely, the lactalbumen and the caseinogen, varies at different periods of life and under changing circumstances. There is nearly always an increase of lactalbumen in infant's food demanded by the increasing age of the infant. This lactalbumen may be obtained very readily and in a suitable form from whey. The caseinogen may be obtained from milk. With an emulsion, the ingredients and amounts of which have been properly collected for a given case, there is no need to add cereals. Pasteurization of such an emulsion when made from fresh, clean materials is needed only if the emulsion is to be sent to a distance. After Pasteurization the material will stand transportation for long distances and yet remain sterile. Samples have been sent from the laboratory in Boston to Vienna and have arrived fresh. The doing away with Pasteurization removes certain objections that militate against the use of heat-prepared foods.

Selection of Wet-Nurse.—Dr. L. Emmett Holt, of New York, said that it is a matter of surprise to many that it should be so difficult a problem to provide a suitable food material for infants. Those who have had experience with the selection of a wet-nurse soon learn to realize how difficult it is to obtain even the proper quality of food for an infant when it is supplied in Nature's own way. It may be necessary sometimes to try as many as ten or twelve women before a suitable nurse, especially for a delicate child, can be obtained. It is no wonder, therefore, that the modification of milk for infant feeding is a very difficult matter and may require under delicate conditions the greatest amount of care in order to secure a suitable article. It must be admitted that breast-milk is the ideal food for the infant. All substitutes must imitate it. The nearest approach to it can be obtained by some modification of fresh cow's milk. The proportions in which the various ingredients exist in cow's milk are so different from those of mother's milk that considerable modification may be required. The oldest idea, and it has proved not unsuitable in numberless cases during the centuries, was to add water and a certain amount of sugar for the taste. The effort at present is to bring cow's milk more nearly to the average proportion of mother's milk.

Infant Food Formulae.—No single formula for the modification of milk will do general duty for all infants indiscriminately. The result of investigations has been not to prepare a food, but rather a method of feeding. The endeavor is to find the elements that are in unsuitable proportions for a given child and then to modify the milk so as to render it digestible and nutritious. In an individual infant suffering from indigestion, it may not be the milk itself, but some ingredient of it which is indigestible. The fats or the proteids, for instance, of a given sample may prove indigestible. If the errant ingredient can be found, its reduction in quantity may make the food digestible once more. For a long while, despite the theoretic promises of this method, success in its use was not very marked. The future looks brighter, however, for infant feeding now that we understand the practical difficulties as well as the theoretically-correct principles.

Four Elements of Success.—There are four factors that make for successful infant feeding with modifications of cow's milk. First, one must have the best fresh milk; too long a time must not have elapsed since it has been obtained from the cow; special precautions must have been taken to keep it clean, and it should have been preserved on ice from the moment of the milking until it is to be used. Second, there must be intelligent cooperation. Definite and minute directions must be given in writing as to the quantities to be employed in the preparation of the infant's food and the times of feeding. Third, personal supervision is necessary to see that orders are carried out. Fourth, every routine of the nursery must be scrutinized. Every point of sanitation must be carefully looked to, the conditions of air and light and cleanliness and clothing and the household surroundings must be examined.

Infant Indigestion.—The digestive disturbances of infants can be divided into two general classes. The indigestion of healthy infants and that of unhealthy infants. In healthy infants all digestive disturbances resemble one another more or less and can be treated on certain general principles. Of the digestive disturbances of unhealthy infants, the name is legion. Nothing is more puzzling or full of surprises than the many-featured phases of digestive symptoms that occur in infants once their digestive function has become chronically affected.

Method of Milk Modification.—For the rational modification of cow's milk, the approximate composition of ordinary milk must first be ascertained and then what is needed in addition to this for the infant's nutrition. At different periods of its life the child will need varying amounts of certain ingredients. The simplest method of preparing these modifications seems to be to take the milk, as it can be ordinarily obtained by a city family. In ordinary bottled milk the cream rises to the top and enables us to recognize what proportion of fatty material is contained in the food, as it is prepared for the infant. During the first few months of life the ordinary infant should receive about one-half milk and one-half cream. This can be best obtained by taking the upper third of the bottle of milk as it is ordinarily supplied by city dairies. During the second period

of the baby's life, that is, from about three to nine months an increase of the proteids is needed with about the same amount of fat, though proportionately to the whole of the food taken by the infant this represents a decrease in the fats. For this the upper half of the bottle of milk should be employed. After the ninth month the baby can be fed with the whole milk. As the baby grows the quantity of food given should be increased. This can be done by increasing the amount given at each feeding without any other modification than that suggested for the different periods. It is often true that delicate children are kept on too low a diet of proteids, because of too great dilution of the milk.

Standard Food Formula.—The food of an infant should not be ordered on general principles according to its age or weight. The digestive condition of the infant is much more important as regards the regulation of the quantity and quality of food that it should take than anything else. The infant's appetite should not be abused. Needless to say it should not be fed every time that it cries. The first symptom of digestive disturbances should be carefully looked for and precautions taken at once to prevent their becoming inveterate to the slightest degree. As soon as fretfulness and sleeplessness assert themselves something should be done immediately to avoid the digestive disturbance that threatens. The first food prescription given an infant should be considered experimental rather than definite. It is much easier to give too much than too little food. Begin with low percentages of all the ingredients and raise these as it seems necessary rather than the opposite course. An excess of fat especially is liable to disturb the infant's digestion and bring on the train of symptoms which may lead irretrievably to the obstinate indigestion that precedes marasmic conditions.

Breast-Fed and Artificially-Fed Infants.—In the discussion Dr. J. S. Winters, of New York, said that the contrast between the breast-fed and the artificially-fed infant is most striking. While the nursing child is almost never sick, the artificially-fed infant seems almost never to be well. It is the exception to find a healthy child that has been fed on the bottle. Statistics seem to show that while 8 per cent. of breast-fed infants die before the end of the first year, 51 per cent. of artificially-fed infants perish before they reach the same age. These are the statistics for private families. In institutions the bottle-fed infants fare still worse. In the Charité Hospital at Berlin from 59 to 93 per cent. of the infants under treatment die. At Budapest, where the same class of infants are in a hospital, only 15 per cent. of the infants die because mothers are required to nurse their own children, or wet-nurses are supplied. There is no question, therefore, but that as far as possible human milk should be the food of the young infant.

Cereals in Infant's Food.—Clinical experience as well as our theoretic knowledge of the infant's digestive organs make it clear that the addition of cereals to the infant's diet is irrational. The nearest approach to mother's milk is cow's milk. It has about the same ingredients and in nearly the same proportions and, moreover, it is of animal origin and so is a more natural food than any vegetable product. One of the great difficulties in city life is to obtain cow's milk, pure and fresh. There would certainly be much less difficulty in the feeding of infant children in our large cities if we could always obtain fresh cow's milk. Digestive disturbances begin as a result of the ingestion of low-grade, contaminated milk and then almost any food, no matter how suitable, becomes impossible of digestion for the child.

Natural Milk.—It must be remembered that many infants bear ordinary, absolutely unmodified cow's milk very well. For such infants dilutions will do harm because they will prevent the infant from obtaining its full complement of food as easily as it should. If fresh milk can be obtained it is better to give it raw than Pasteurized. Undoubtedly the application of heat to milk, either at high temperatures or at lower temperatures, over long periods, produces changes in the milk which make it difficult of digestion. When cream is to be added to milk gravity cream and centrifugal cream amount to the same thing.

Cereals Not Irrational.—Dr. Chapin said that cow's milk is a radically different substance from mother's milk. The more the two forms of milk are studied, the more is this realized. Cereals are not any more foreign to the infant's digestive organs than is cow's milk itself. The talk about its irrationality because of its being a foreign substance is therefore groundless. There is no doubt that it does good by making the coagulum of the milk finer and less tenacious. This mechanical advantage every one admits. If the cereal gruel be dextrinized before being added to the milk there need be no fear about its digestibility. When the coagulum of the milk is finer much more of the surface of the clotted portions is exposed to the action of the digestive juices. Not only this but the curd of milk produced by digestive action in the presence of a cereal are always much more porous than when cereals are absent, and so the gastric juice is able to penetrate them.

Mother's Milk Not Sterile.—Dr. R. G. Freeman said that mother's milk is usually not sterile. Frequently her nipple is infected and is cleaned only by the baby's tongue. Even in the human breast some bacteria exist and find their way into the milk.

The Curdling of Milk.—Dr. T. M. Rotch, of Boston, said that the reason for the differences between the coagulum of cow's milk and that of mother's milk is the presence of more caseinogen in cow's milk. The caseinogen might easily be increased in mother's milk, however, and then the curd produced by the digestive juices would be coarse and tenacious. Every doctor has seen mother's milk thrown up in reasonably large, tenacious curds.

ORIGINAL ARTICLES.

THE SURGICAL IMPORTANCE OF JAUNDICE.

BY ARCHIBALD MACLAREN, M.D.,
OF ST. PAUL, MINN.

THE early theory regarding the causation of jaundice was that in most cases it was due to some mechanical obstruction. This position which has been proven to be to a great extent erroneous has led surgeons of the past to place altogether too much importance on the presence or absence of this symptom when studying the diseases of the biliary passages. Look at any of the more recent works on general medicine, for instance, Allbutt's System or Pepper's American Text-Book of Medicine, and see the long list of diseases in which jaundice is a symptom, as for example, typhoid, pneumonia, dengue, influenza, cerebrospinal, intermittent, relapsing, typhus and yellow fevers, pyemia, abdominal aneurism, heart disease, leukemia and all the different forms of pancreatitis, peritonitis and hepatitis.

Of course it is very true that the jaundice associated with many of these diseases is, as a rule, of a very different character from that observed in the true obstructive cases. As William Hunter says, "The jaundice is usually less intense in its character from that met with in mechanical obstruction, being frequently evidenced by a slight yellowish or greenish-yellow discoloration of the skin or conjunctivæ, rather than the dull golden yellow or green color of true obstructive jaundice.

The following case is so unusual in this connection that I will give Dr. Solberg's clinical report in full. Mrs. T. R. W., aged thirty-one years, born in this State of Swedish parents, herself mother of two healthy boys. Has always with few exceptions during early childhood enjoyed good health. During the last week of pregnancy she complained of constant itching all over her body and her skin was noticed to be of a muddy hue, but as her general health was good especial attention was not paid to the itching. Labor and puerperium were uneventful except that a sore on one leg, caused by scratching, took on an erysipelatous appearance on the fifth day of her lying-in period, but soon healed kindly under appropriate local treatment. When her baby was a few months old she went away visiting her parents in a neighboring town, where she spent the summer in apparently good health. She returned to her home in St. Paul in September, when the peculiar muddy complexion already mentioned, seemed a good deal more marked, but as she claimed to be in excellent health and had an abundant supply of milk for her child, no medication seemed necessary.

Later on she consulted me for nightly diarrhea, when I found that symptoms of obstructive catarrh of the bile ducts had developed. Her conjunctivæ and skin were deeply greenish-yellow, some itching, foul-smelling, nightly diarrhea, stools clay or cream-colored, urine very dark, etc., but the general health was excellent, appetite and strength good, mind cheerful. I then commenced to prescribe remedies generally used under such circumstances and she continued to take them for a long time, but without apparent benefit. She continued to nurse her baby and appeared to feel perfectly well, except for her nightly diarrhea. Suddenly one day, when the baby was about eleven months old, she was seized with severe pain in the hypochondriac region extending down somewhat into the right lumbar region. This was diagnosed as biliary colic and controlled by hypodermics of morphine. I also gave directions that stools be examined carefully for calculi. As pain continued without intermission, except when controlled by morphine, for a number of days, and some fulness and great tenderness developed in the regions mentioned, with a temperature ranging between 100° and 103° F. and no stones could be found in the feces, I deemed a consultation necessary. Drs. P. Ritchie and A. MacLaren saw the case with me, and both concurred in the diagnosis of obstructive jaundice and thought that, if she did not improve in a few days, an operation would be imperative. No improvement taking place she was removed to Bethesda Hospital for operation. She was then deeply jaundiced, and had been so continuously for eight months or more; the stools were clay-colored; the urine was very dark, and there was continued pain in the right hypochondrium and lumbar region; also some emaciation.

Mrs. W. was operated on April 9, 1897. An incision was made in the right semilunar line and a perfectly normal biliary system demonstrated. No inflammatory thickening or adhesions, no obstruction. An inflammatory mass, however, was palpated in the right loin continuous with the lower end of the right kidney. An incision in the back over the crest of the ilium opened a large appendicial abscess. Every touch of the knife was followed by excessive hemorrhage as is often the case in chronic jaundice. Mrs. W. lived only a few hours after the operation, dying from the shock of hemorrhage and acute sepsis. A post-mortem was made by Dr. Solberg and myself, when a post-cecal appendicial ab-

scess was demonstrated, drained into the incision in the back. There was absolutely no disease of the liver or the biliary passages found. The bile was normal in quantity and quality and there was no obstruction in the ducts, or inflammation of the mucous membrane lining the biliary passages. This case is quite unique, no similar case being reported that I have been able to find in quite an extended and fairly thorough study of the literature.

Since this paper was prepared a case of marked jaundice of considerable duration was reported by Groose of Sioux Falls, South Dakota, as having been observed by him when he was a resident of Mercy Hospital, Chicago, several years ago, where an appendicial abscess was found at the time of operation. The cause of all these forms of jaundice is still an unsettled question, but is probably due to the influence of septic germs which are circulating in the blood and in the lymph in these cases.

Dr. Henry G. Graham, in an article just published in the *New York Medical Journal,* entitled "Microbes—What are They?" gives the result of his experiments which go to prove that the protozoa, which are frequently found in the fluids of the body and can readily be seen with the naked eye, are the hosts from which under proper conditions are developed living microscopic subdivisions or buds which, when stained, give every evidence of being streptococci, staphylococci, and perhaps tubercle bacilli. If this proves to be true what a wide field for research this opens up in the study of disease and its causation, of which our small subject is a very infinitesimal part.

But to return to jaundice; Hunter further says, when speaking of toxemic jaundice, as, for example, infectious jaundice, icterus gravis and Weil's disease, "In a number of these cases, indeed organisms of varying character have been described as occurring in the liver, there is hardly any reason to doubt the microbic origin of toxemia jaundice." Dr. George Adami, of Montreal, in his very interesting and scholarly article on latent infection and subinfection, has proven that many of the forms of chronic inflammation, such as are found in cirrhosis of the liver, in hemochromatosis and probably in pernicious anemia, are due to the presence of bacteria which were being taken up and more or less perfectly killed by the tissues, but at the expense of their own vitality. He says, "As a consequence of chronic inflammatory disturbance in connection with the gastrointestinal tract, there may for long periods pass in through the walls of the stomach or of the intestine a greater number of ordinary bacteria inhabiting the tract, and, while the bacteria undergo the normal and inevitable destruction by the cells of the lymph-glands, the liver, the kidney, and the other organs, the excessive action of these cells and the effect on them of the bacterial toxins, liberated in the process of destruction, may eventually lead to grave changes in these cells and in the organs of which they are a part—changes of a chronic nature.

Adami quotes Dr. Fütterer of Chicago, as follows: "He was able to gain the bacillus prodigiosus from the pelvis of the kidney two minutes after injection into the jugular vein of the dog, while, inoculating animals with the pyococcus aureus and the bacillus prodigiosus, and following Biedel and Kraus he collected the bile from a cannula inserted in the common duct and gained abundant culture of these micro-organisms from the bile within two or three minutes after inoculation into the left side of the heart. Thus, I am led to conclude that where the number is not too great, the liver tissue is capable of wholly destroying and digesting the bacteria. Where, however, this function of the liver-cells becomes exhausted by the taking up of excessive numbers of the bacteria, it is possible for the bacteria to be discharged or secreted into the bile in a still living state." Adami further says, "These observations appear to me to clearly demonstrate that, while one of the functions of the lymphatic glands is to take up and destroy bacteria circulating in the lymph, a function of the liver, both as regards its endothelium and its cells, is to take up and destroy such bacteria as are introduced by leucocytes into the venules of the portal system and gain entrance into the portal blood, while similarly a function of the kidney parenchyma, more especially of the convoluted tubules, is to remove bacteria circulating in the systemic circulation."

These conclusions are of especial interest in studying the causation of cholecystitis and the microbic origin of gall-stones. Last winter I presented to the Minnesota Academy of Medicine a paper on the relationship between cholecystitis and gall-stones, in which I contended that in the great majority of cases cholecystitis was the disease and the stones only products or symptoms of the disease. The bile is an excellent culture medium and cultures of the colon bacillus and the ordinary pus germs, but particularly the bacillus typhosus, have been found by many observers in the gall-bladder of persons suffering from typhoid—in other cases years after a typhoid attack, and a few times in cases that had never had the disease; and Cushing of Johns Hopkins reports that on two occasions he has artificially produced gall-stones by injection of the culture into the gall-bladder of animals. Of course, the inflammation may extend from the intestine, but probably the great majority come from the blood in the manner that Adami has pointed out.

But to return to the infectious nature of jaundice, in the *Zeitschrift für klinische Medicin,* Band 36, three cases of pneumonia are reported in which icterus had been present and in which the colon bacillus was found in the bile. While in other cases that had no icterus the bile was sterile. Of course, the liver is the cesspool or filter of the body and has the power of filtering

out or killing infectious germs which are circulating through the blood incased in its leucocytes. At times under a sudden strain, or depending on the number or intense virulence of the germs or of the poison produced by the germs, the liver-cells probably become swollen and temporarily compress the finer biliary channels and thus produce more or less well-marked attack of jaundice. Whether this theory is correct or not this mild jaundice is of no practical surgical importance, except perhaps to attract our attention to the liver and gall-bladder. Aside from its being of no positive value as a symptom, it is not even a negative sign, for many cases where extensive disease of the biliary passages, such as exist with every case of cholecystitis with and without gall-stones, have been shown to exist for months and years without a sign of jaundice at any time in their course.

Mayo Robinson reports 167 cases of cholecystotomy in which he found gall-stones present 140 times; in 100 of these cases no jaundice had been present at any time during the course of the disease, and in most of the cases where it had been present it was only very slight in amount or present during but two or three of the attacks of colic.

During the past year I have performed 13 operations upon the gall-bladder and bile-ducts; two of these were exploratory in character and no disease was found; in one, adhesions existed between the gall-bladder and the pylorus. The remaining 10 all showed gall-stones in greater or less number, and all of these, with one exception, showed evidence of cholecystitis, yet in not one of them had jaundice ever been present at any time during the course of the disease. Several of these patients had had the disease for several years, having suffered many attacks which were supposed to be due to the passage of gall-stones.

Mild and transient attacks of jaundice occasionally accompany cholecystitis and catarrhal inflammation of the bile-passages by the obstruction produced by plugs of mucus, although I think that such a result is rare. Fagge thinks that catarrh of the bile-ducts never gives rise to enough swelling of the mucous membrane to produce jaundice. If such a result is ever produced it would be most likely to occur, accompanying a catarrhal inflammation of the duodenum, by obstructing the common duct where it passes obliquely through the intestinal wall to discharge at the ampulla of Vater.

A more pronounced form of jaundice is seen in connection with Weil's disease in acute yellow atrophy and with abscess of the liver. In the first of these the jaundice is the most striking symptom of the disease. It usually shows itself about the second or third day of the disease. It rapidly increases until the patient is quite yellow at the end of twenty-four hours. It lasts about fourteen days and disappears slowly. In acute yellow atrophy of the liver the jaundice does not last quite as long, but is usually quite intense in character. In abscess of the liver the jaundice is as a rule not well marked, but this is only one of the times in which there is any indication for surgery, unless the first be complicated, as it sometimes is, by cholecystitis. In abscess of the liver the indication, as in any other abscess, is to reach and drain the abscess cavity. When superficial, and if adhesions have been found, this is a very easy matter. But in deep abscesses, or if the abscess is on the superior surface of the liver, so that it is necessary to reach it through the pleural cavity, it is often a very difficult and dangerous procedure. These abscesses, if neglected, have at times a deep and a superficial cavity connected by a small and usually a tortuous channel. If the deep cavity is not reached, you may not relieve your patient. I remember opening a large superficial abscess of the back, several years ago, in a very sick man, who died a few days after the operation. A post-mortem demonstrated just such an abscess, very imperfectly drained, in the center of the liver.

When we come to well-marked and persistent jaundice, the great majority of these cases we find to be suffering from carcinoma of the liver. This is a very common disease. Between the years 1885 and 1893, inclusive, 4200 autopsies were performed at Guy's Hospital, and in 3 per cent. of this number either primary or secondary carcinoma of the liver was found.

W. Hale White, in speaking of this subject, says, "About half the patients who during life present symptoms of carcinoma of the liver are jaundiced; and this nearly always means that enlarged carcinomatous glands in the transverse fissure are pressing on the common bile-duct. But in some cases the pressure is due to the primary growth, especially if it be in the head of the pancreas; and occasionally enough of the hepatic ducts in the liver may be compressed by nodules of new growth for jaundice to appear. Or there may be primary cancer of the bile-ducts. It is extremely important to bear in mind that by far the most frequent cause of long-standing jaundice is cancer of the liver, which always produces deeper jaundice than any other common disease; thus, patients suffering from cancer present in the most extreme form those symptoms which are due to circulation of bile in the blood and its absence from the intestines. The jaundice, too, is permanent; the only exceptions to this rule are those excessively rare cases in which, although the patient has cancer of the liver, the jaundice is due to a gall-stone in the common duct, which is either passed on or slips back. The skin, deeply and slowly stained by bile, gradually becomes more and more green and ultimately assumes a peculiar earthy, dark-green tint, which, especially if the patient is aged and wasted, is almost diagnostic of cancer of the liver. The other effects of bile in the blood are also evident; the urine is very dark and has a

yellowish froth, the numerous scratch-marks show the intense pruritus. The bitter taste in the mouth is very unpleasant, the sweat may be bile-stained, and if, as often happens from secondary deposits in the lungs, the patient gets bronchitis or pneumonia, the expectoration may be yellow. There are few things more characteristic in medicine than to see an aged, gray-haired patient extremely wasted, with dry, dark-green skin hanging in loose folds, lying perfectly still, so drowsy that he is more dead than alive. If we turn down the bedclothes the liver may be seen deforming the shape of the abdomen, and it will be noticed that the sheets are stained yellow by urine or sweat. The absence of bile from the intestine causes indigestion and constipation, and the motions are pale, smell horribly, and contain much undigested fat."

The surgery of cancer of the liver is very unsatisfactory. The disease is, in my experience, very aggravated and the end is hastened by even an exploratory operation. Cholecystotomy and drainage give relief except in cancer of the common duct. Cancer of the gall-bladder, which is almost always found in cases when gall-stones have existed for years, should be removed if the liver be not too extensively infiltrated.

One of the more intense forms of jaundice is found in connection with stone in the common duct. Fenger and Osler have both described the ball-valve-like action of such stones, which accounts for the intermittent jaundice which usually accompanies this condition. The presence of a stone in the common duct, either floating or impacted, almost always produces cholangitis or infective catarrhal inflammation of the bile-ducts. Robeson describes it as follows: "The usual history is one of spasms for several years without jaundice; then comes a more severe seizure followed by temporary icterus. If the gall-stone pass, there is an end of the trouble; if not, the next attack of pain is probably followed at once by a shiver and by all the symptoms of an "ague fit," the temperature frequently reaching 104° or 105° F. After it passes off the skin is deeply tinged and the jaundice may persist, although inconstant in degree; it rarely, however, disappears completely between the attacks; there is usually a slight icteric tinge of the conjunctivæ, even though the interval between the attacks may be one of weeks or of months. The rigors may be repeated daily or at irregular intervals."

My conclusions, therefore, are: (1) That slight attacks of jaundice are of comparatively little surgical importance, and that the majority of surgical disease of the biliary passages have no jaundice at all. (2) That persistent jaundice especially if progressive is usually a contraindication. (3) While on the other hand intermittent, deep jaundice, especially if associated with chills and a rise in temperature, denotes a stone in the common duct which urgently demands removal.

THE HYDRIATRIC TREATMENT OF TUBERCULOSIS.[1]

By J. H. KELLOGG, M.D.,
OF BATTLE CREEK, MICH.

(Continued from page 732.)

In the employment of general cold applications in cases of pulmonary tuberculosis it is necessary to observe with care certain precautions.

1. A tonic cold application should never be made when the surface is cold, when a chill is impending or when the patient feels chilly, nor when the temperature is high.

2. Cold applications should not be made to the entire surface at the same instant until the patient has been trained by carefully graduated partial cold applications, in which the whole surface is gone over by applications to small territories in succession. The danger of pulmonary congestion from retrostasis is thus avoided. This is especially necessary in cases in which there is a hemorrhagic tendency. When the application is made to small areas in succession, as in the wet hand-rubbing (Fig. 5), cold mitten-friction (Fig. 1), cold towel-rub (Figs. 6, 7, 8), reaction is produced in each part before proceeding to the next.

WET HAND RUB

Fig. 5

Thus the general retrostasis is avoided and pulmonary congestion is not produced.

3. The intensity, duration and frequency of applications must be accurately adapted not only to the patient's ability to react, but to his power

[1] Read before the American Climatological Association, Washington, D. C.

to digest and assimilate, the aim being to stimulate constructive metabolism more than destructive change. A loss of weight indicates the necessity for rest from exercise and diminished intensity, duration or frequency of the cold application.

4. In applications for the lowering of temperature, all the antithermic measures such as are used in typhoid fever and other infectious fevers, as the Brand bath, the cooling pack, cannot be safely employed because of the intense internal congestion produced by these measures and for the further reason that the resistance of the body and its heat-making capacity are greatly reduced, so that only mild measures are tolerated. The neutral bath, wet hand-rub, wet towel-rub, administered carefully, and at temperatures ranging from 85 to 92° F., are best suited to the purpose. The cooling head-compress and the cold abdominal and the cool chest-compress are also useful as a means of producing fever.

5. Great care should be taken to avoid producing prolonged chill at any time, and especially in the beginning, measures which produce retrostasis by causing contraction of the blood-vessels of the entire cutaneous surface are not well tol-

COLD WET TOWEL RUB TO CHEST.

Fig. 6.

erated except in the incipient stages of the disease.

6. The patient's weight, general strength, appetite and temperature are matters which should be carefully studied in relation to the treatment. An increased loss of weight indicates the necessity for rest and decrease in the intensity, duration or frequency of the treatment. Loss of appetite and of strength indicate the necessity for the adoption of the same measures. Fever inter-

COLD WET TOWEL RUB TO ARM.

Fig. 7.

dicts short cold applications and requires the application of prolonged tepid measures.

7. An aggravation of any of the patient's symptoms indicates a necessity for the modification of the treatment. A proper management of hydriatric treatment secures very prompt or almost immediate alleviation of symptoms. A contrary result should be accepted as evidence for the necessity of a change.

8. By the employment of these general principles, we may confidently expect to secure some degree of alleviation of all the symptoms even in the worst cases; in the average case, great improvement and a lengthening of life amounting to many months and sometimes several years; and in favorable cases, suppression of the fever and the night-sweats, improvement in appetite and weight, and decided gradual lessening and final disappearance of the cough and expectoration, restoration of strength and general vigor and, finally, disappearance of the bacilli and complete suppression of all symptoms.

The patient should continue the treatment in a modified way after the disappearance of all the symptoms not only for a few weeks but for months, even years. In fact, the habitual employment of the daily cold bath may be regarded

as one of the best of all safeguards for persons who have been cured of the disease by hydriatric measures. After having made use of most of the above described measures for the last twenty-five years and in a large number of cases, I feel

COLD WET TOWEL RUB TO FEET.
Fig. 8.

no hesitation in saying that they are capable of accomplishing more for the radical cure of tuberculosis than any or all other known measures.

Symptomatic Measures.—While the various distressing and threatening symptoms present in this disease are for the most part relieved by the general treatment here outlined, special applications of various sorts render great service. The general symptoms for which the above treatment acts almost as a panacea, are anemia, nervous and muscular weakness and emaciation. The relaxation and unhealthy condition of the skin likewise rapidly disappears under the powerful vasomotor gymnastics of cold-water applications. Various localized and special measures are needed to meet particular conditions and symptoms. The following measures recommended for special conditions have all been tested and proven valuable in the hands of the writer and his colleagues in dealing with the conditions for which they are commended.

Cough.—The chest-pack at night (Figs. 9-12). Sipping hot water when the paroxysm is threatened, in cases in which the cough is due to irritation in the throat. If hard coughing is due to the viscidity of the secretion, copious drinking of warm or hot water will afford relief. When the cough is exceedingly troublesome, the chest-pack should be worn during the day as well as at night. The chest should be rubbed well, first, with the hand dipped in water at 50° F., then with the dry hand, before the pack is applied. In cases in which emphysema exists, with cavities in which secretions accumulate to the detriment of the patient, the cough being too weak to expel the secretion, the expulsive efforts of the lungs may be reinforced by slapping the chest with the hand or towel dipped in ice-water just before applying the pack. These measures should not be applied if there is danger of hemoptysis.

Through the nervous and vascular relations of the skin with the internal viscera it is possible by means of thermic applications to the surface of the body to exercise almost complete control over the general movement of blood in the body and local blood-supply as regards both volume and rate of movement of blood. Every internal viscus is represented from the surface of the body by an area with which it is in reflex relation through the vasomotor centers. The cutaneous areas related to the lungs comprise the skin covering the chest, especially the anterior portion of the chest, the shoulders, the anterior lower surface of the neck, the arms, especially the palms of the hands. Applications to this surface produce effects differing according to the temperature, duration, and mode of procedure. A short cold application produces contraction of the bronchial vessels, which is followed after the withdrawal of the application by dilatation with increased activity of the bronchial vessels and increased movement of the blood through the lungs. Prolonged cold applications produce prolonged contraction of the bronchial vessels provided the sensibility of the cutaneous nerves is maintained by occasional short applications, by rubbing with warm dry flannels, by the removal at frequent in-

ROLLER CHEST PACK. (First Step.)
Fig. 9.

tervals of the cold application long enough to allow reaction to occur, or by allowing the cold compress to become slightly warm before removal.

A heating compress, that is a cold compress well covered and allowed to accumulate heat until it attains the ordinary temperature of the skin or a little more, causes first a brief contraction of the bronchial arteries, followed by a dilatation and increased activity of the nutritive vessels of the lungs with diversion of blood into the intercostal veins, thus facilitating the movement of blood through the lungs and diminishing passive congestion and encouraging leucocytosis. Short hot applications to the chest-wall divert blood from the bronchial vessels into the collateral vessels—the internal mammary and the intercostals.

By alternate hot and cold compresses, a sort of pumping action may be operated upon the lungs. The cold application contracts the small vessels, thus emptying the tissues, while the succeeding hot application instantly dilates the vessels, admitting a new supply of blood, which by the succeeding cold application is forced onward into the venous circulation. The effect of a hot application can be renewed as often and as long as desired by brief cold applications at intervals of ten or fifteen minutes. The effect of cold applications may likewise be prolonged by brief applications of heat at short intervals.

The chest-compress not only combats the irritation and passive congestion to which the cough and expectoration are due, but lowers temperature and by increasing the movement of healthy blood through the parts improves the nutrition of local cells, removes and neutralizes the toxins by with their resistance is lowered or destroyed and especially encourages leucocytosis, the most effective means by which the body can combat the bacillus.

The effect of the chest-pack in relieving the cough is often magical. Patients who have been almost entirely deprived of rest by a troublesome night cough are often at once so relieved that abundance of refreshing sleep is obtained by the simple application of the chest-pack at bedtime. In cases in which the circulation is feeble the wet towel should be covered with oiled muslin, mackintosh or gutta-percha tissue, in addition to the flannel wrappings. Either the roller or the square chest-pack (Figs. 13-16) will be found convenient for use in cases of this sort.

Expectoration.—When expectoration is scanty, copious water-drinking is advantageous by increasing the secretion of the pulmonary mucous membrane. The viscid secretion is so diluted that it may be easily expelled. The chest-pack diminishes excessive secretion by relieving congestion, at the same time relieving irritation and resulting cough when expectoration is not present.

Pain.—Short fomentations followed by the heating compress are the best means of relieving pain. Pleuritic pain sometimes requires the application of a tight bandage about the lower part of the chest. If necessary, hydriatric applications may be applied over the outside of the bandage. Fomentations applied to the chest should be short, not more than five to eight minutes, and as hot as can be borne. The heating compress should be prepared with very cold water, should be wrung very dry, and should be instantly applied when the hot compress is removed.

Hemorrhage.—This grave symptom is not, of course, always easily controlled. Even hydriatric applications sometimes fail because of the large size of the ruptured vessels giving rise to the hemorrhage. The best measures are hot applications to the lower extremities, as the hot leg-pack, cold compresses applied to the chest, consisting of a folded towel or six or eight thicknesses of cheese-cloth. Very hot applications applied to the cervical spine, covering especially the vertebræ prominens. Solly has called attention to the fact that atropine, if used in sufficiently large doses (1/50 of a grain), sometimes renders service in checking hemoptysis by lowering blood-pressure. Blood-pressure may be lowered to almost any degree desired by the hot blanket-pack and by vigorous friction of the skin. By these means the blood-vessels may be dilated to such a degree as to contain nearly two-thirds of all the blood in the body. In the application of friction the rubbing should be outward from the heart, or following the distribution of the arteries, so as to lessen the movement of the blood toward the heart and the chest. Reflex

ROLLER CHEST PACK. (Cheese Cloth in Place.)
Fig. 10.

contraction of the pulmonary vessels may be induced by ice to the hand and over the neck. Care must be taken to keep the arms warm so as to favor hyperemia of these parts and collateral anemia of the lung. No part of the surface, with the exception of the chest-wall, should be allowed to become chilled. It is often better to apply a fomentation to the whole back to relieve the bronchial arteries by diverting blood into the intercostals while, at the same time, contracting the vessels of the lung by cold applications to the front chest, preferably a cheese-cloth compress wrung out of ice-water and renewed every minute. If the application is long continued, the skin should be rubbed with dry, warm flannel at intervals of five to ten minutes to maintain cu-

ROLLER CHEST PACK COMPLETED. (Front View.)

Fig. 11.

taneous sensibility which is essential for the stimulation of the vasomotor centers.

Dyspnea.—Paroxysms of dyspnea are best relieved by short, hot applications to the spine, the hot foot- or leg-bath and the hot leg-pack. Hot sponging of the chest and spine are excellent measures. When due to disordered digestion, fomentation over the stomach should be administered. A warm enema when constipation exists. A fomentation to the spine with cold bag or compress over the stomach is useful in dyspnea due to distention with gas.

Irritation of the Throat.—This condition, which appears in its most aggravated form in cases of laryngeal tuberculosis, requires the throat-pack, which may be worn night and day. Hot-steam inhalations are sometimes of service, but generally fail in tuberculous laryngitis.

Chill.—This symptom requires rest in bed, wrapping in blankets, hot bottles to the sides and feet, hot-water drinking. The hour at which the chill arrives having been ascertained, the patient should be ordered to bed half an hour or an hour before the time at which the chill is expected to occur. Rubber-bags filled with hot water or hot bottles should be placed at the sides and feet. He should be wrapped in warm blankets, and, if necessary, a dry pack should be administered in the ordinary way. The occurrence of slight perspiration will do no harm, provided it is not induced too rapidly. Great care should be taken to avoid subsequent chilling after perspiration has occurred. If the intensity of the chill be lessened, the reactionary fever will be less intense.

Fever.—When elevation of temperature is a marked symptom, the neutral bath may be employed with advantage and with perfect safety at a temperature of 92° to 95° F. for an hour. The best time for the bath is half an hour to an hour before the time at which the temperature usually reaches its greatest intensity. By this means the febrile process may be controlled and as the application is renewed from day to day, the febrile movement may be found to yield more readily. The chest-pack also assists greatly in reducing temperature. When the temperature of the patient rises at night to 101° F. or more the compress should be lightly wrung in the application of the chest-pack. Thus, considerable antipyretic effect may be secured. Free water-drinking aids temperature reduction by eliminating the bacterial toxins to which the temperature elevation is due.

Night-Sweats.—Profuse perspiration is but the natural cooling off of the fever. Suppression of chills and fever is quickly followed by this appearance of the night-sweats. Sponging the whole cutaneous surface with water as hot as can be borne just at bedtime is an excellent means of lessening the cutaneous activity and securing comfortable sleep.

Cardiac Disorders.—More or less cardiac disturbance is likely to occur in tuberculosis as a result of the great diminution of the respiratory area. Hypertrophy or dilatation of the right heart is frequent from this cause. Excessive action of the heart should be controlled by rest in bed, and the application of the ice-bag over the heart, or the cold precordial compress. The application may be continuous in severe cases; in other cases the compress should be applied every other hour. Short applications of the cold precordial compress are equally valuable in cases of cardiac weakness shown by feeble, frequent pulse, cyanosis, and laborious respiration. The duration of the application should be from fifteen to twenty minutes twice a day. Later the time may be extended to forty minutes or even one hour, forenoon and afternoon. There is no agent which exercises more powerful control over the heart than the cold precordial compress.

It acts with greater promptness and certainty than digitalis or any other so-called heart tonic. Short applications slightly energize the heart; prolonged applications exercise an equally marked sedative influence.

Digestive Disturbances.—These are generally of the atonic variety. The stomach is dilated in a large proportion of cases of pulmonary tuberculosis. In fact there is no doubt that digestive disorders, with resulting failure of nutrition, lay the foundation for the disease in a great majority of cases. The futility of stomachics and so-called digestive stimulants of various sorts, which are commonly used in tuberculosis, has been well shown by Skeritt.[1] This observer found by post-mortem examination that the activity of the pancreatic extract in consumptives was diminished fifty per cent. The diastatic examination of the saliva in living consumptives showed depreciation of the salivary secretion to the same degree. These observations agree with those of the writer as to the condition of the saliva in tuberculosis. Its activity is almost invariably diminished. This fact accounts, without doubt, in large measure for the emaciation of consumptives and their inability to digest starchy foods and fats. Digested foods are required and the application of such measures as will improve the metabolic activity of the secreting glands.

The most useful foods are such as have been subjected to the preliminary digestion of the starch, either by means of heat or by vegetable diastase. Malt is useful as a food rather than as a digestive agent. It should be taken freely to the extent of several ounces daily. Maltose is easily converted into levulose, the form in which sugar enters the blood. Starch in the form of mushes and starchy vegetables is digested very slowly while it ferments and sours easily. Starch converted into achroodextrine by exposure to temperature sufficiently high to brown it slightly, is, next to maltose, the most assimilable of foods. Toast and zwieback and roasted or browned rice are excellent examples of well-cooked farinaceous foods. Sweet fruits are still better, presenting sugar in the form of glucose already for absorption and assimilation. Grapes and grape-juice are especially rich in glucose, also sweet apples, figs and most other sweet fruits. Malted milk and cream, malted nuts and various malt and heat-digested cereals are useful in these cases as fat-producers.

Cold water is the most valuable of all remedies for this purpose. The general cold bath promotes glandular activity in all parts of the body, and it promotes the activity of the peptic glands, as has been clearly shown by examination of the gastric fluid, and by its general restorative effects promotes all the metabolic processes. The application of the ice-bag over the stomach for half an hour before eating increases the digestive power of the stomach as shown by the increase of appetite. The CO_2 compress is still more effective as a peptic promoter. The prolonged application of the hot compress after eating is as active in promoting digestion as the ice-bag before the meal. A quarter of a glass of ice-cold carbonated water may be taken half an hour before the meal with advantage. These measures are infinitely superior to any medicinal remedies which can be administered in promoting the appetite and digestion. Predigested foods should be used in conjunction with the measures suggested.

Vomiting.—This symptom is generally the result of violent coughing. A dry dietary, eaten slowly while lying down, is best. The patient should recline half an hour before eating in order

ROLLER CHEST PACK COMPLETED. (Back View.)

Fig. 12.

that the breathing may become tranquil and the food should be eaten very slowly to avoid hurried respiration. When cough is excited reflexly by irritation of the sympathetic, the hot and cold trunk-pack or the hot chest- and trunk-pack, or both combined if necessary, should be applied half an hour before food is taken, and the duration of the compress should be two hours, or at least an hour, after the completion of the meal, the patient remaining in the meantime in a horizontal position. In mild cases a compress extending from the umbilicus to the clavicle applied half an hour before eating will be found sufficiently quieting to the sympathetic centers to prevent both cough and vomiting. A hot and cold trunk-pack consists of a towel wet

[1] Year-Book of Treatment, 1896.

in cold water, wrung dry, and wrapped around the trunk, a hot bag over the stomach, and a warm, dry, folded blanket tightly enveloping the whole. The hot and cold chest-pack is applied in the same way, only the hot application is made to the back instead of to the front of the chest.

Diarrhea.—When due to tuberculous lesions of the intestines or mesenteric glands little more can be expected than moderate mitigation of the condition. If considerable pain is present, very hot fomentations should be applied for fifteen minutes once a day. This should be followed by the heating compress to be worn night and day, changed once in four hours. The hot enema is sometimes useful.

In conjunction with hydriatric treatment, massage, carefully graduated and prescribed exercise, manual Swedish movements, Swedish gymnastics, out-of-door life, and climatic change, may be expected to accomplish all that can be done in the curative treatment of pulmonary tuberculosis. If some assistance may be obtained from the local use of antiseptics and the administration of creosote and other measures, the chief reliance must be placed upon the powerful physiological measures which have been outlined, and which experience has proven to be capable of accomplishing results which are truly marvelous when compared with the results ordinarily obtained in this most unpromising class of cases.

Winternitz reports the cure of a large percentage of the cases which have come under his care at his institution at Kaltenleutgeben, the charming suburb of Vienna. Dr. Riley, Superintendent of the Colorado Sanitarium, of Boulder, Colo., has reported a series of fifty-one cases of recovery, all of which were treated by hydriatric methods combined with rational hygienic care and the excellent climatic advantages of the Rocky Mountain region, at an altitude of about 5000 feet. At the Guadalajara Sanitarium, Guadalajara, Mexico, most excellent results have been obtained by the same means. Scores of persons are to-day leading useful lives as the result of the employment of these rational measures at the institutions named, who would have unquestionably been buried long ago without the treatment administered.

Of the 240 cases treated within the last three years at Boulder Sanitarium 160 have been cured or very greatly and more or less permanently improved. A large proportion of the remaining 80 have been temporarily helped to a marked degree, even though the disease was far advanced. It is very rare indeed that patients who are subjected to the treatment outlined in this paper do not very quickly show signs of improvement in increased appetite, lessened fever, lessened night-sweats, and gain in flesh. Patients not infrequently gain at the rate of two to three pounds a week for several weeks in succession. The cough is lessened, strength as well as weight improves, and not infrequently the patient finds himself at the end of a few months looking as well and as free from pain and discomfort as ever in his life. Slight dyspnea is often the only symptom which remains behind. The permanence of this symptom being the natural result of the lessening of the respiratory area occasioned by the pathological processes characteristic of the disease.

It is my firm belief that the general adoption of hydriatric measures in the treatment of pulmonary tuberculosis by the profession at large, and especially the application of these measures to the disease in its incipient stages, would result in saving at least nine-tenths of the sufferers from this disease from the untimely death to which almost every one is doomed under ordinary medical management.

[To be concluded.]

PERNICIOUS ANEMIA: REPORT OF A CASE.

By G. R. TROWBRIDGE, A.M., M.D.,
of Buffalo;
Attending Surgeon to Fitch Hospital.

In 1855 Addison in his well-known paper on "Disease of the Suprarenal Capsules" first brought to the attention of the medical profession the disease idiopathic or pernicious anemia, speaking of it as follows: "For a long period I had from time to time met with a very remarkable form of general anæmia, occurring without any discoverable cause whatever—cases in which there had been no previous loss of blood, no exhausting diarrhœa, no chlorosis, no purpura, no renal, splenic, miasmatic, glandular, strumous or malignant disease."

Biermer in 1868 discussed at length the pathology of the affection, and Wilks, Lebert, Channing, and Gusserow have all made additions to the literature on the subject. Fortunately it is a comparatively rare disease, for in spite of study and investigation by both clinician and pathologist the cause has to the present time remained in obscurity.

Geographically, progressive pernicious anemia is widely distributed. At one time it was thought to be especially frequent in the Cantons of Switzerland owing undoubtedly to the fact of its being confused with the other serious anemias.

Etiology.—This is very obscure, there being no known or appreciable cause. As yet it is impossible to say whether the disease is produced by a defective hemogenesis or hemolytic process. A number of authorities among whom are Stephen Mackenzie and F. P. Henry believe that there is a fault somewhere in the process of blood-making and that from this deficiency the red corpuscles become especially prone to changes and degeneration. In spite of all theories the etiology is as yet extremely unsatisfactory, and it will only be by patient and careful study and investigation both ante- and post-mortem that the cause of the disease will be disclosed. That there is a continuous, uninterrupted and constant change in the blood is well

known, but we are still in the dark as to the reason for these changes.

Morbid Anatomy.—There is pallor of the entire surface, also the lemon-green tint in the skin. Sometimes, and usually, there is extreme emaciation; at other times, but comparatively little loss of the subcutaneous fat; the former condition being due, I believe, to the long duration of the disease, while the latter occurs in cases running a rapid course. The liver and spleen are enlarged, the heart muscles of a pale color, lungs normal and stomach normal, excepting perhaps a slight fatty degenerative change Other lesions have been described, but none of them are constant, such as changes in the sympathetic ganglion (Queckett) and sclerosis of the posterior columns of the cord (Lichtheim).

Symptoms.—An individual who has apparently been in perfect health gradually develops symptoms which seem at first to be those of a simple anemia. The onset of pernicious anemia is sometimes sudden but more frequently very gradual, and the patient is often unable to give the exact time of the beginning of his illness. The skin slowly becomes pale, gradually assuming the lemon-green tint characteristic of the disease, and is most marked at first on the face, after slowly extending over the entire surface of the body. There is a very perceptible weakness, and marked dyspnea on exertion due to the heart's action being very rapid. Vertigo and headache and ringing in the ears are often though not always present. Numbness of fingers and toes is one of the first indications. The organs of digestion gradually become disturbed, there is enlargement and engorgement of both the liver and spleen, edema of the extremities and, toward the end of the disease, as a rule, extreme emaciation. The finale is described as follows by Addison: "The debility becomes extreme, the patient can no longer rise from bed, the mind occasionally wanders; he falls into a half-torpid and prostrate state and at length expires; nevertheless and to the very last and after a sickness of several months' duration, the bulkiness of the general frame and the amount of obesity sometimes present a most striking contrast to the weakness and exhaustion observable in every other respect."

The Blood.—In the blood we must look for a certain confirmation of the diagnosis of pernicious anemia. Oligocythemia is always present as a principal feature and is as a rule very extreme. The relation between the percentage of hemoglobin and number of red corpuscles is disproportionate, the corpuscles being greatly decreased in number, while the hemoglobin remains comparatively stationary. The red corpuscles fall to about one to two million per cmm., and often lower, while the hemoglobin ranges from 18 to 40 per cent. A fresh blood slide shows numerous macrocytes. These are a constant feature of the disease and it is possible that in cases where there is a high percentage of hemoglobin it is due to the excessive number of the large red corpuscles. In addition to these are found numerous microcytes or dwarfed red corpuscles and also those having irregular form, *viz.*, poikilocytes. Ehrlich has shown that two varieties are constantly present: (1) Normoblasts about the size of an ordinary red corpuscle, containing a nucleus which stains deeply and is situated eccentrically in the cell; (2) very large forms or megoblasts with large faintly stained nuclei. There are, as a rule, but comparatively slight changes in the leucocytes.

In the early stages there is marked dyspnea which increases as the disease progresses, and is due probably to the inability of the blood to carry oxygen. The pulse is small and rapid; murmurs are heard in the cardiac region. Hemorrhages into the skin and mucous membranes occur occasionally. The lips and tongue are pale and there is nausea and vomiting of more or less frequency and severity. Constipation is usually extreme and requires enemata. The urine shows no important changes. The specific gravity is low and the urea and uric acid somewhat increased.

Diagnosis.—The points on which to base a diagnosis are as follows, and in every suspected case include an examination of the blood. (1) Greenish-yellow tint of the skin. (2) Dyspnea and rapid pulse without pulmonary symptoms and a proportionate rise of temperature. (3) The intense oligocythemia. (4) The presence of macrocytes and microcytes. (5) The steady and uninterrupted progress of the disease toward a fatal termination and the inefficiency of treatment.

Prognosis.—This is always unfavorable. The course of the disease is steadily toward a fatal ending. Cases have been reported to be cured, but I am inclined to believe they are cases which have merely had an intermission and have then disappeared from the attendant's observation, or else there has been an error in diagnosis. My own opinion is that cases of true pernicious anemia do not recover.

Treatment.—Arsenic is the only drug which seems to have a beneficial effect in these cases, and then, although it does, it is only slight and not permanent and only temporarily checks the progress of the disease. Fowler's solution in increasing doses to the tolerance of the individual; arsenious acid used in the same manner is the best form of the drug for these cases. Complete rest in bed; light and nutritious diet; light massage for insomnia; digitalin and strychnine for weak heart's action; oxygen inhalations for the dyspnea. Bone-marrow is sometimes of temporary benefit, and in using this latter I think the preferable way to give it is to spread a certain quantity of marrow, freshly scraped from bones, on a thin slice of toast. I believe this to be better than the preparations of marrow found on the market. Transfusion of blood has been tried

but, like all other forms of treatment, is of only temporary benefit.

Fortunately cases of pernicious anemia are rare. A case which came under my observation during the summer of 1899 was of twofold interest, first, because my patient was an intimate friend and, secondly, because it was the first case I had ever seen. The history is as follows: G. K., aged forty-nine years, American, medium height and weight. Latter part of June, 1899, came to my office complaining of general malaise, temperature 99.5° F.; pulse 100; on walking or making any exertion the latter increased to 140 or 150; appetite poor, bowels irregular; skin on face showed slight change in color resembling that produced by jaundice. As he had had one or two such attacks about a year previously, although not so severe, I advised him to give up business and take a complete rest in the country, together with tonics and a nourishing diet. I saw him again at the summer resort where he was staying about one week later. He had gained about one and a half pounds in weight, but his general appearance and condition were worse than when he left home; the slightest exertion caused palpitation and extreme dyspnea. The discoloration of the skin had assumed more of a greenish tinge and was extending over the shoulders and arms. The appetite was poor; bowels torpid and liver somewhat enlarged. He also had slight hemorrhage from the rectum. I advised his return to Buffalo where he came during the first part of July.

I was now convinced I had an extremely serious case to deal with and was undecided as to whether it was a malignant growth, Addison's disease, or pernicious anemia.

The patient attended to his business for a day or two and after this was confined to his house and to his bed the greater part of the time until his death. Before the blood examination was made he was seen in consultation by Dr. C. R. Jewett, and at that time malignant disease was eliminated and it was left to the blood examination to determine between Addison's disease and progressive pernicious anemia. The blood examination was made by Dr. H. G. Matzinger and showed 2,500,000 red corpuscles and 35 per cent. of hemoglobin. There was extreme poikilocytosis, a failure in the piling up formation of the red corpuscles and numbers of macrocytes.

This showed positively that the case was one of pernicious anemia. Perfect rest was at once directed and a plain and nutritious diet ordered together with increasing doses of arsenic beginning with grain 1/30 t. i. d., also tonics and stimulants. The bowels were kept regular by means of enemata and cathartics. Two weeks after a second examination of the blood was made showing an increase in the percentage of hemoglobin, but a decrease in the number of red corpuscles, also the same conditions of degeneration and lack of efforts at normal repair. During this period all kinds of unfavorable and uncomfortable symptoms arose; extreme hyperesthesia of the surface of the body, marked distention of the bowels from gas and consequent colic. There was loss of appetite, nausea and vomiting, obstinate constipation and insomnia. About this time my patient was seen by Drs. John Parmenter and D. W. Harrington and in addition to the treatment already instituted bone-marrow was ordered. At this period the emaciation became very marked. The diagnostic lemon-tint of the skin extended over nearly the entire body; there was constant edema of the hands and feet and all the former symptoms were greatly exaggerated.

Examination of the blood made by Dr. C. S. Jewett on the dates mentioned shows distinctly the steady progress of the disease. August 14th: Red cells 937,500, hemoglobin 37 per cent.; August 26th: red cells 765,000, hemoglobin 25 per cent.; September 10th: red cells 595,530, hemoglobin 25 per cent. From this point the progress of the disease was rapid and it was necessary to resort to the hypodermic use of morphine two or three times a day. At no time during the course of the disease were there important changes or abnormal conditions present in the urine. An examination of the blood on November 1st showed a further diminution in the number of corpuscles and in the percentage of hemoglobin. Death occurred November 14th. No post-mortem was made.

In presenting this paper the point I wish to emphasize is this: In cases of apparent chlorosis and primary anemia in which there is present the greenish tint of the skin, together with dyspnea, palpitation, and general malaise, one should not depend on symptoms for the diagnosis, but should let the blood examination decide whether one is dealing with either of these diseases or with a case of pernicious anemia.

SOME OBSERVATIONS ON AFFECTIONS OF THE GALL-BLADDER.[1]

By FRANK Le MOYNE HUPP, A.M., M.D.,
OF WHEELING, W. VA.;
ATTENDING SURGEON TO THE CITY HOSPITAL.

That the surgery of the gall-bladder including gall-stones has received too little attention at the hands of the medical writer until recently, no one will deny. From a purely surgical standpoint the subject has never before been brought to the notice of this society. A. W. Mayo Robson[2] advances the proposition that "as soon as gall-stones give serious trouble their removal

[1] Read before the West Virginia State Medical Society, Morgantown.

[2] Robson, Diseases of the Gall-Bladder and Bile-Ducts, first ed., preface.

by operation is the most rational method of treatment. It is one that can be safely supported, since it is only from the complications, which in many cases of cholelithiasis arise sooner or later, that any danger after operation need be apprehended.

The following cases have come under my observation during the past year and a half:

Case I.—Choledochotomy; removal of one large stone by crushing; suture of the ductus communis, drainage, recovery. Gained thirty pounds in three months.

Mrs. M., Woodsfield, Ohio, aged thirty-six years, was admitted to the City Hospital, referred to me by Dr. J. R. Parry, February 1, 1899. A sister suffered with epilepsy, otherwise antecedent history good. No previous morbid personal history. She married, at the age of twenty-four, and has had three children, normal confinements, and one miscarriage. Present illness began about three years ago with what she describes as "a bilious attack," constipation, nausea, vomiting and epigastric pain. The cramps lasted several hours, but her recovery was complete apparently. Since that time she has had several attacks, each one a little more severe than the preceding one. She never noticed any icterus until she was six months pregnant with her last child, which was born eight months before her admission to the hospital. At this time she had an attack of cramp-like pain, for the most part localized under the right costal border, radiating toward the epigastrium and back under the right shoulder-blade. The icterus was slight, but the pain was severe. Since the birth of her child she has not been well, suffering with a constant soreness under the ribs on the right, has lost flesh and strength, her food did not agree with her and the appetite was poor. Her stools have had a gray appearance, and the color of her skin was sallow. The pain varied in intensity, and it often required an opiate, and when very severe she was compelled to go to bed for several days at a time, and at these times her icterus was deeper and the urine a dark brown.

On admission, the patient was poorly nourished and anemic. The skin and sclerotics were slightly icteric, and her stools were the color of lead and decidedly hard. Heart showed an anemic blowing murmur in the third left space. Urine 1018, no albumin, sugar or casts, acid in reaction, and bile pigment abundant. Blood contains 71 per cent. hemoglobin. Palpation reveals very marked tenderness over the gall-bladder, and a slight sense of resistance, but no tumor. This patient was given three weeks of preliminary treatment. She was placed on a peptonate of iron with arsenious acid after her meals. A heaping teaspoonful of the natural Carlsbad Sprudel salt in eight ounces of water a half-hour before her breakfast; in addition to this she succeeded in disposing of from four to five pints of hot distilled water daily. She was given daily a hot bath and massage treatment. Her general condition improved and she was in good condition for operation by February 21st.

Operation.—Under ether narcosis an oblique incision, about five inches in length, was made parallel to and about two inches below the free border of the ribs on the right. The incisura between the right and the anterior lobe of the liver was felt for and found, and the resistance felt on palpation before opening the abdomen was found to be a mass of dense adhesions overlying the gall-bladder. These were ligated and cut and after some blunt dissection an atrophied gall-bladder was exposed. The peritoneal cavity was walled off by large gauze compresses and the gall-bladder opened. It bled freely, was very thick, and contained about an ounce of very dark viscid bile and some granular detritus. Exploration of the interior of the gall-bladder led me to think that the lumen of the cystic duct was obliterated, but later I succeeded in passing my finger down through the cystic duct some distance, and then with the help of Fenger's probe located the offending stone well within the foramen of Winslow. The cystic duct was so contracted that it was impossible to dislodge or even map out the territory about the stone. The blunt dissection was most carefully continued outside of the bile-passages so that with strong light and good retraction the common duct was exposed and incised immediately above the stone, which had been partially crushed between the thumb and finger. Through this incision Fenger's scoop was passed and the crushed particles of a large gall-stone removed. The fragments weighed 83 grains.

With a fine needle and fine iron-dyed silk five stitches were used in closing the incised duct. A large rubber drainage-tube was inserted into the open gall-bladder and a small tube carried down to the neighborhood of the repaired duct. Some strips of sterile gauze were placed in the wound along the tubes, the gall-bladder sewed to the parietal peritoneum and aponeurosis and the wound closed. The tube was placed in a four-ounce bottle with its end immersed in an inch of twenty-per-cent. carbolic solution, and this bottle was pinned to the outer dressing. The small tube was removed in twenty-four hours, the larger one was left *in situ* for eight days, draining and syphoning large quantities of bile.

The wound healed primarily, the site of the drainage tube granulating, so that by March 26th there was not any leakage. The patient was discharged cured April 1st. In three months she gained forty pounds. She became pregnant one month after leaving the hospital, and in January of this year gave birth to a healthy boy without incident. She is now well.

Case II.—Cholecystectomy, with removal of ten large stones; choledochotomy one large stone removed. Recovery.

Mrs. J. W. H., of Marshall County, West Virginia, aged forty years, married and the mother of six children. Admitted to the City Hospital May 7, 1899, by her family physician, Dr. H. T.

Ford. There was no morbid family history. Her previous health had been good before the onset of her gall-bladder trouble. For the last eleven years she has suffered periodically with what she calls "pleurisy attacks," pain referred to the right side, and extending backward beneath the shoulder-blade, occasionally radiating upward into the right shoulder and axilla. These attacks would come as often as once in three or four months for the first six or seven years, the longest interval having been nine months, while carrying one of her children. She never coughed or expectorated, and was never jaundiced. For the past year she has suffered more than in the previous nine years. The attacks have become more frequent, so that she has been incapacitated for doing her household duties, has been obliged to resort to opiates for the relief of her pain, and has lost flesh and strength.

November 6, 1898, or about five months before admission to the hospital, she was seized with a chill, followed by a high fever and an attack of very sharp pain over the gall-bladder, radiating toward the stomach and posteriorily beneath the right scapula. This pain was not relieved entirely by a grain of morphine, but continued the following day and gradually diminished, leaving the patient much prostrated and decidedly jaundiced.

In the five months she lost over forty-five pounds and has suffered periodically with intense pain. She was never entirely free from soreness, her icterus gradually deepened, and her life was a burden to herself and a source of constant solicitude to her friends.

On admission the patient weighed 138 pounds; the skin was a deep bronze color, mucous membranes and sclerotics a decided yellow; pulse 110, afternoon temperature 100° to 101° F.; tongue furred and heavily coated; urine the color of strong coffee; microscopically negative; specific gravity 1021, acid in reaction, with a trace of albumin. Stool clay-colored and hard. Area of hepatic dulness increased, a very decided resistance beneath the ninth rib on the right and exquisite tenderness, rectus muscle rigid and abdomen somewhat distended. Patient was the picture of despair and the lines of her face showed too well her five months of intense suffering.

Operation.—April 8th, ether narcosis. An incision six inches in length was made parallel to the right costal margin. Adhesions were everywhere present. The general cavity of the peritoneum was well protected by large crash compresses. The gall-bladder was nowhere to be seen. The groove where it might be expected was well to the right so that after double ligation and division of many vascular bands the edge of the liver, yellow and rough, was identified and retracted upward with difficulty. After some little time was consumed in blunt dissection of part of the omentum and stomach-wall from the under surface of the liver, the thickened, elongated gall-bladder could be felt well embedded in the under-surface of the substance of the liver. On incision there escaped a mucopurulent and bile-stained fluid and with it ten stones were removed.

Exploration demonstrated that the gall-bladder was nothing more than a blind pouch having no communication whatever with the cystic duct, nor could one be made, as the cystic duct was found to be obliterated for about three-quarters of an inch beyond this blind sac. The gall-bladder was removed. I felt confident that the operation thus far had not removed the obstruction. Blunt dissection was carried downward with the aid of a portable incandescent lamp and Allis' blunt dissector. Palpation of the hepatico-duodenal ligament revealed a hard mass in the common duct. After the identification of the vein and artery as far as it was possible, an incision was made in what seemed to be the point of junction of the cystic and common ducts. Fenger's spoon was inserted and the stone removed. The common duct was found dilated at this point, yet the stone seemed anchored in some way, for it was removed with difficulty. A tube of moderate caliber was inserted into the incised duct and the closure of the wound was in every way similar to Case I. In less than twelve hours the bile poured out copiously, saturating the very ample dressing, binder and bed-linen. The tube was removed on the sixth day, and by the end of the third week no bile stain was observable at the sinus. Patient was discharged cured June 10th. She weighed 186 pounds in February of this year, contrasted with 138 pounds on admission to the hospital the previous May.

Case III.—Cholecystotomy; choledochotomy, removal of a friable stone, morphine habitué, cholemic secondary hemorrhage, death.

Mrs. E. S., aged thirty-eight years, married. Mother died of Bright's disease, had been operated on for floating kidney. While pregnant with her first child, a boy four years old, she suffered with the vomiting of pregnancy and three months before the birth of her baby had her first attack of biliary colic. The pain continued and was sufficient to demand the daily use of morphine. It seemed to reappear paroxysmally for more than three weeks. The hepatic colic, working in its sequelæ upon a constitution already infirm and impoverished, left behind a nervous adynamia, and it was for the relief of this condition and the soreness about the gall-passages that the morphine was unfortunately continued. The habit fastened itself upon her, although the patient vainly endeavored to fix a daily allowance, but it was always with considerable leeway for emergencies, as in almost all like cases. Her hypodermic syringe became her *vade mecum*. Constipation, early confirmed, grew to be an annoying symptom. Insomnia, interrupted by a fitful sleep precluded any real refreshing. Her stomach developed that peculiar sense of gnawing described by De Quincy, as if produced from the presence of a reptile. Her paroxysms of

pain became more and more frequent, and her icterus deepened to a bronze. It was in this condition that she was admitted to the City Hospital in December, 1899, where she undertook a treatment for her morphine habit. I saw her for the first time January 16, 1900, and found the epigastrium and region of the gall-bladder very sensitive on palpation, but no tumor could be felt. On account of the sharp attacks of hepatic colic and the profound cholemia, I advised immediate operation.

Operation.—January 17th, under ether and chloroform narcosis a transverse incision was made. The structures seemed unduly vascular. The peritoneum was very much thickened and inflamed. The liver was very much enlarged and had a fatty, mottled appearance, as though the seat of cirrhosis. Some adhesions were separated and the gall-bladder was exposed. It was distended and pale in appearance. After guarding the cavity of the peritoneum, a cholecystotomy was done, and immediately there gushed out a large quantity of milky fluid containing no bile pigment. It came from the bile-duct, for the quantity was far in excess of the gall-bladder's capacity.

Courvoisier[1] found in literature ten cases of hydrops of the biliary ducts, which were filled with a watery, colorless, or slightly mucoid fluid which did not possess any of the characteristics of bile. In these ten cases the entire system of the biliary tract was filled with a hydropic fluid of this nature. In not one of the ten cases was the obstruction due to stone, but to tumors within or outside of the common duct, or to obliteration of the duct in one case. He explains the acholia by assuming that cessation of the secretions of bile may, under certain circumstances, be caused by high pressure on the liver-cells, due to the stagnation of bile behind the obstruction. In this case and in one reported by Fenger the acholia was partial and was caused by a stone, and this phenomenon seems to be remarkable, as Fenger's case and the one under consideration are the only two known to me which have been reported.

The common duct was exposed and incised, and with the aid of the spoon several large fragments of stone were brought into view. The common duct was widely distended and there was no evidence of bile pigment in its wall. Further search and probing was rewarded by finding more of the friable fragments of the gall-stone. There was some troublesome bleeding from the surface of the liver, where an adhesion had been separated. This was promptly arrested, as well as the bleeding from all other adhesions, a tube inserted into the opening in the dilated common duct, and the gall-bladder sewed to the parietal peritoneum. Strips of gauze were passed down along the side of the tube, a large absorbent dressing applied and the patient removed from the table. Time of operation, two hours.

[1] Fenger. *Am. Jour. Med. Sci.*, Feb., 1896, p. 147.

During the first twenty-four hours following the operation a quart of pure bile escaped through the tube, and from this time on there was a most copious secretion. The pulse at the end of twenty-four hours was 104, temperature and respiration normal. A grain of morphine was given the first night to allay the pain. The nurse was instructed to give a half-grain of morphine when the occasion required, but strange as it may seem the patient did not ask for the opiate after the end of the second day.

In the two weeks preceding the operation she had suffered with two attacks of fainting while in bed. One of the attacks had followed an injection of some gold preparation which she had been taking under the direction of another physician, but whether or not they were the result of the hypodermic injections, I am not prepared to say. They were characterized by a quick, irregular heart-action, sighing respiration, and would pass off in less than an hour, leaving the patient rather prostrated for the rest of the day. Three days after the operation, January 20th, she was seized with such an attack. She lay for an hour in a cold clammy sweat with the eyes partly closed, pulse ran up to 120, temperature subnormal, and extremities cold. The wound was dressed and the strips of gauze removed, and only a very little dark blood could be seen on the bile-stained strips. Otherwise the wound looked perfectly healthy. This condition of shock was combated with dry heat and stimulation, and she reacted kindly. The supposition was that the syncopal seizure was similar to those which she had experienced prior to the operation. The stomach retained nourishment, and the bowels moved freely and much flatus was passed in response to enemata. The fecal matter contained some bile, and the urine was losing its coffee color. There was some very slight tympanitic distention, yet the vermicular contractions of the bowels could always be heard on auscultation.

January 21st and 22d, the bile continued to flow freely and the icterus seemed to be clearing. The pulse varied from 96 to 120. The skin felt natural except when she was threatened with one of the fainting spells. The area of hepatic dulness appreciably diminished, and at intervals on the 19th, 20th and 21st, she seemed well and bright and planned much for the future. She had no pain and required no morphine, yet, when one of the sinking spells came on, she presented the appearance of a patient in great shock.

Early on the morning of the 23d she was very restless, asked frequently for water and ice, and at times would vomit the clear water, which was slightly bile-stained, without much effort. Several times during the day she asked for morphine, and each time a quarter of a grain seemed to satisfy her. About three o'clock in the afternoon she was seized with one of the syncopal attacks, and while every effort was made to arouse the weary heart, she grew steadily worse and died at nine o'clock in the evening.

Autopsy.—A post-mortem examination of the abdominal contents was made. The stitches were removed and the site of the operation exposed to view. There had evidently been a progressive secondary hemorrhage, as large quantities of clotted blood were found between the diaphragm and the liver, and extending beneath the liver and posteriorly as far back as the spine, but not entering the peritoneal cavity. The wound was clean and the intestines were not even congested. There was no sign of peritonitis. The hepatic abrasion spoken of was clean and there was not any clotted blood about it. The region of the incised gall-bladder and bile-ducts in through the foramen of Winslow was not stained and it was demonstrated that no considerable bleeding had come from the immediate field of operation. For the most part it seemed to have been a general oozing; perhaps more came from the denuded surfaces where adhesions had been broken and separated, yet no one place or vessel was responsible for the large amount of blood which was found. It should be remembered that every adhesion of any size at the time of the operation received proper attention, and before closing the wound more care than usual was observed in searching for bleeding vessels.

While this patient had never presented any of the symptoms which might have placed her in the category with those of the hemorrhagic diathesis, unless it was that she flowed excessively at the time of her menstruation, this diathesis is well known in icterus gravis and is also found in the icterus resulting from gall-stones. Dr. Fenger speaks of it as a grave complication, and Courvoisier found it in fifty-eight patients, in most of whom operation was not performed and in whom the hemorrhage was severe and often fatal. He collected reports of six cases in which hemorrhage from the wound of operation in the gall-bladder had a fatal termination. "He warns us," says Fenger, "to search the history of the patient and make careful examination all over the body in order to ascertain whether or not a predisposition to hemorrhage exists, either from the mucous membrane or in the subcutaneous tissues; and in case the patient presents the symptoms to abstain from operation, which is likely to prove fatal on account of the uncontrollable hemorrhage from the wound of operation or from other organs. In some cases, however, in which no symptom of hemorrhage preexisted the operation has been followed by fatal hemorrhage, not from the operation wound, but from other portions of the body. It seems almost as if the operation brings into active existence a latent hemorrhagic condition."

Merman reports that Czerny lost seven patients out of forty-three upon whom he operated for diseases of the biliary tracts. Three of the seven deaths were caused by cholemic secondary hemorrhage, which in one case occurred from the intestines, entirely independent of the wound of operation.

Case IV.—Gall-stones; cholemia, ulceration and perforation of the common duct; no operation; septic peritonitis; death.

Dr. A. L. Hupp of Cherry Camp, West Virginia, one of the most brilliant and highly respected members our State Society has ever produced, died at his Harrison County home June 16, 1899. It was my sad privilege to be present in consultation with Dr. Louchery, the day before he died. Dr. Louchery has kindly written the following letter regarding the case:

"I was called to see Dr. Hupp May 29, 1899; he had been suffering for four or five days with spasmodic colicky pains in the region of the gall-bladder and thought he had passed about three gall-stones, and later did pass three or four small stones. He was very much jaundiced and suffered at intervals from nausea. He had administered to himself hypodermically from one-half to one grain or even one and one-half grains of morphine a day to relieve the pain. Diagnosis of impacted gall-stones was made. At times there was a remission of pain, so that we hoped he was improving. Stools were pasty, whitish and clay-colored; no appetite, tongue furrowed whitish, made yellow by vomited matter. Every day or two he appeared to relapse into a more serious and depressed condition, and finally died, suffering the most excruciating agony, on June 16, 1899. He vomited toward the last with the persistency of intestinal obstruction. There was active delirium and his condition was septic.

"The Doctor had had some four or five similar attacks, the first immediately succeeding the meeting of our State Medical Society in Wheeling in 1896. Another attack the next winter succeeding a very severe siege of typhoid fever during the summer and fall of 1893. In fact, he had been an invalid ever since the attack of typhoid fever. The treatment relied upon chiefly was pure olive oil and sulphate of soda, but they were without effect utterly. The very strange part was that so intelligent a physician could so persistently have refused the aid of the surgeon until moribund."

Case V.—Gall-stones, ulceration and perforation of the common duct; shock and septic peritonitis; no operation; death.

Mrs. S. W., aged seventy-eight years; healthy antecedents, mother of five children. Sixteen years ago she had some symptoms of obstructions of the bowels, the description of the attack answering very well that of fecal impaction. She had suffered from constipation, indigestion and colic for years, and had experienced occasionally some pain and soreness in the right hypochondrium. She had frequent attacks of vomiting throughout the winter, lasting part of a day and always attended with some pain in the right side, but she did not even speak of this to the members of her family, not wishing to annoy them. She has been very active of late years and enjoyed very good health. She was seen by her physician, Dr. E. C. Meyers, April 15th, sitting up in a chair suffering from what she called indigestion and colic. She thought little of the

attack, but confessed that it was worse than it had ever been before. The pain over the gall-bladder interfered with her breathing, and was not relieved until morphine was injected. An examination by Dr. Meyers showed some resistance under the ribs on the right side, and there was some slight distention of the bowels, nausea and vomiting. April 17th at night she was seized with very sharp pain in the epigastrium and in less than an hour exhibited symptoms of shock and collapse. Morphine and cardiac stimulation tided her through the night, but her physician made a grave prognosis, watching at her bedside through the night and feeling that her advanced age and the marked evidence of shock precluded the possibility of any surgical interference. I saw her the following morning in consultation. The patient was icteric, with a distended abdomen, temperature 103.5° F., pulse 136, small and thready, and vomiting. So great was the distention that nothing diagnostic could be made out in the right hypochondrium. It was evident that there was a peritonitis and that the patient was fast approaching a moribund condition. She died that night.

Autopsy.—A ruptured common duct was found and two friable stones loose in the peritoneal cavity near the seat of rupture. No effort had been made on the part of Nature to wall off the large quantity of seropurulent bile-stained exudate. The gall-bladder contained thirty or forty small, black, crenated stones, each about the size of a French pea and not faceted. The intestines were markedly distended and were covered with some recent catarrhal exudate.

Case VI.—Ulcerative perforation of one of the bile-ducts; symptoms of peritonitis; no operation; recovery.

James McK., aged twenty-nine years, carpenter. No morbid family history. No previous morbid personal history. About ten years ago he had an attack of indigestion about every five or six weeks which incapacitated him for a day or so. They were characterized by colicky pain in the epigastrium, radiating to the right, nausea and vomiting. No icterus. He had been living in the oil fields for the last five years where the food is not always what it should be. He had no further trouble until about a year ago, when there was some return of the old attacks. During the last ten months he had four or five rather severe attacks of pain, always localized over the stomach, lasting about a day and leaving him sore for several days. There was some icterus noticed at these times. April 24th of this year he awoke in the morning with an attack of indigestion and pain in the right side. As the day wore on the pain became more severe, and he called his physician, Dr. E. A. Hill, of Wolf's Summit, Harrison County. He continued ill all day Wednesday and in the evening about nine o'clock he was seized with violent, lancinating pain in the right side extending up into the right arm and shoulder. His pulse was rapid and his temperature was 102° F. Hypodermic injections of morphine relieved the pain, but only temporarily. He was seen by Dr. Louchery in consultation with Dr. Hill Thursday morning, April 26th, and at this time in addition to the other symptoms there was some distention of the abdomen, vomiting and constipation.

The patient was brought to Wheeling on a stretcher and admitted to the City Hospital where I saw him, with Dr. Hill, Friday morning, April 27th. At that time his pulse was 110, temperature 99.5° F. He seemed to be suffering acutely from general abdominal pain with its point of maximum tenderness over the region of the liver. The abdomen was distended and the right rectus muscle was rigid. There seemed to be an effusion or a sense of resistance over the gall-bladder. There was also noted a want of symmetry in the two sides of the chest along the axillary line and over the liver. Over this fulness there was marked tenderness on palpation. Percussion yielded a dull note high up into the axilla on the right. An occasional moist râle and a suspicion of bronchial breathing could be heard over this area. He coughed and expectorated a rusty mucopurulent sputum. The acute tenderness and extreme distention of the abdomen made a positive diagnosis entirely out of the question. His treatment consisted in the application of a pneumonia jacket, whiskey, strychnine, and peptonized milk. A high enema given at ten o'clock in the morning was not effective.

I did not feel justified in suggesting surgical interference without more light in the direction of a positive diagnosis. For there seemed to be as many indications at that time favoring beginning hepatic abscess as there were toward perforative ulceration of the gall-passages. In the evening his pulse was 140, respirations 32, temperature 102° F., and he complained of feeling chilly, but distinct rigors did not occur. Another effort at moving the bowels was rewarded by the patient passing a perfect storm of flatus and a large quantity of soft lead-colored feces. By morning the pulse was 120 and of better quality, temperature 99.5° F., and breathing less frequent. Monday morning, April 30th, the tympanitis had subsided in large measure. The pulse was 108 and the general aspect of the patient improved. Tuesday the distention had almost entirely disappeared, bowels were moving freely, pulse 90 to 96, temperature normal, and respiration 20 to the minute. The rectus muscle was still rigid, but a mass about the size of a hen's egg could be felt over the gall-bladder, which was tender on deep pressure. May 8th he sat up out of bed for the first time. His icterus began to clear up, and his convalescence was assured.

There seems to be little doubt as to the diagnosis in this case: An ulceration with leakage of one of the bile-passages, causing a local peritonitis, with a complicating pulmonary congestion —perhaps some pneumonia. I feel satisfied that had he been subjected to an operation at the

time when it seemed most needed, the day following his admission to the hospital, the case would have terminated fatally.

61 Fourteenth Street.

MEDICAL PROGRESS.

Clinical and Bacteriological Diphtheria.—Dr. Winters in the discussion on diphtheria, at the New York Academy of Medicine, said that 104 cases of diphtheria on a hospital staff was a record-breaking number. Henoch in his text-book on children's diseases says that diphtheria is not contagious for adults except under special circumstances. He distinctly states that during thirteen years and a half of his service in the children's department at Berlin, where there were constantly diphtheria patients in the wards, not a single nurse or doctor contracted the disease. Trousseau, whose experience with diphtheria was very large, says in his text-book that diphtheria is very rare in hospital servants. It is, therefore, extremely surprising to find over 100 cases occurring within a few years in the service of a hospital in Boston. The reason for this surprising morbidity, one cannot help but think, is due to the difference between clinical and bacteriological diphtheria. When bacteriological diagnosis came in the number of cases of diphtheria rose very markedly in a very short time. In the Boston City Hospital less than 1100 cases of diphtheria were admitted in four years before the days of bacteriological diagnosis. Recently there have been 1900 cases in a little less than 13 months. Physicians are counseled against the use of large doses of antitoxin. At the Willard Parker Hospital in New York observers have thought they have noticed an increase of mortality as the dosage of serum was increased. Even the most enthusiastic advocates of the serum treatment do not claim that any better results were obtained with large doses than with comparatively small ones. Although it is being insisted more and more that the question of the curative effect of antitoxin is absolutely settled, as a matter of fact there still remains reasonable doubt in this matter.

Dr. W. H. Bergh of New York said that their experience with large doses of serum at the Willard Parker Hospital had not been very favorable. The mortality was not reduced and many more cases of skin eruption occurred than after the smaller doses. Moreover, there was a marked tendency to more frequent occurrence of bronchopneumonia. It must be remembered that the lungs are emunctory organs, as well as respiratory organs. The effort to excrete some of the principles contained in the heterogeneous serum of the horse seems to lower their vital resistance. If, as in Boston, 50,000 or more cc. of serum are injected, 250 cc. of heterogeneous serum must be disposed of by the system. This involves too much labor for the emunctories of the body.

Dr. Rupp said that to the general practitioner diphtheria antitoxin has proved a great disappointment. Personally, he has given up its use except in such cases as those in which parents urged by a mistaken public opinion in the matter insist on the use of antitoxin. In one such recent case a series of the most painful complications ensued after an injection of diphtheria antitoxin.

Etiology and Treatment of Asthma.—On account of the absence of discoverable pathological lesions, sufficient to cause the well-marked symptoms of asthma, there have consequently been a large number of reasonable and fantastic theories advanced in regard to the etiology of this disease. W. A. Wells (*N. Y. Mcd. Jour.*, Oct. 13 and Oct. 20, 1900), after passing in review the several factors which are ordinarily advanced as influencing, at least, the asthmatic attacks, suggests that by reason of the spectacular paroxysmal crises which occur in asthma, provoked as they sometimes are by peculiar and apparently trivial causes and disappearing in an equally unaccountable way, there must be some well-marked psychical factor, and he is further inclined to believe that epilepsy, migraine and angina pectoris possess a number of points in common with asthma. Haig and Schlemmer have strongly urged the uric-acid causation of asthma, on account of the increase of that excretory product in the urine during the attacks. The phenomena, however, cannot be explained on a physical hasis alone, the emotional centers, no doubt, playing an important part. In considering the treatment of the paroxysms fumigations give great relief. A good formula is:

℞ Pulv. stramonii.....
Pulv. belladon. fol...aa. 25.0 (℥j)
Pulv. potassii nitrat.... 6.0 (℥j)
Pulv. opii ..... 1.0 (gr. xv)

Pyridine, a volatile coal-tar product, when employed by inhaling ten or fifteen drops put upon a handkerchief, gives almost instantaneous relief. Another recent remedy highly praised by the French is iodide of ethyl. Morphine and atropine are perhaps the most reliable drugs for this disease. An organic cause must always be looked for, several cases having been found to be induced by irritation of the vagus resulting from pressure upon it by an enlarged thyroid. More frequent and rather common causes are throat and nose lesions, and these must always be sought for. A valuable prescription which is used during the intervals of attacks is:

℞ Ammon. iodid..... 6.0 (℥j)
Ammon. bromid..... 8.0 (℥iss)
Syr. tolut..... 60.0 (℥ij)
Tinct. lobelia.....ad. 100.0 (℥iij)

Dose, one teaspoonful.

On account of the uric acid diathesis the author has used piperazine in a large number of cases

of asthma and believes it to be exceedingly effectual in warding off this affection when given in doses of one gram per day in the form of piperazine water.

Herpes Zoster and Acne Rosacea.—Herpes zoster is an acute inflammatory disease of the skin, running its course in about three weeks and characterized by severe neuralgic pains which frequently subside on the appearance of the vesicles, but may persist for some time afterward. A. Memelsdorf in a clinical lecture upon this disease and acne rosacea (*Med. Standard*, Oct., 1900) says that a central or peripheral traumatism, infiltration of a ganglion or a nerve by a neoplasm, inflammation or any other irritation in any part of the tract from the cord to the periphery of the nerve may evoke a zoster eruption. Kaposi distinguished eight varieties according to the location of the lesion. Since it is a self-limited disease, it is only necessary to treat the symptoms as they arise. Morphine hypodermically may be necessary and phenacetin internally is useful. The best local application is flexible collodion with or without morphine. This markedly alleviates the pain and frequently prevents the rupture of the vesicles, which may result in the formation of ulcers. Acne rosacea is supposed to depend largely upon the use of alcoholic stimulation, but the effect of alcohol has never been positively proven, the real cause of the disorder being probably the accompanying gastric catarrh. Exposure to excessive heat and cold may cause rosacea. In treating this condition it is important that attention must be given to any constitutional or local disturbance. The seborrhea and desquamation must be removed by green soap and water. A ten-per-cent. ointment of sulphur is then applied at bedtime, removed next morning and a soothing application (ten-per-cent. boric acid) rubbed into the face. Lassar's paste may be spread upon the face and left for fifteen minutes, when it is removed and a dusting powder added. The paste may be applied four successive nights. This causes an inflammation and desquamation of the skin, and a bland ointment may then be necessary. Scarification and massage may also be used. Heitzman recommends the following: Calcis ʒss, sublimated sulphur ʒj, water ʒx. Boil down to six ounces and filter. After the face has been thoroughly cleaned and comedones opened, this solution, in a strength of one to ten of water, is used once a day for the first week. The dilution is gradually reduced to one to five. During the day a ten-per-cent. boric acid ointment may be employed.

Lignosulfit in Tuberculosis.—Of all remedies employed in tuberculosis, those which directly reach the alveoli give the most promising results, and lignosulfit, in the opinion of R. Simon (*Therap. Monatschft.*, Oct., 1900), ranks most highly of these. It is a mixture of sulphurous acid with the aromatic ingredients of fir, dissolved to form a brown fluid. A ten-per-cent. aqueous solution is allowed to saturate the air of a room in which the patients must remain one to two hours daily. Improvement soon manifests itself by a change in the physical signs over the lungs and by a gradual disappearance of the annoying symptoms. As a valuable adjunct to the treatment, pulmonary exercises are mentioned; these are especially good when the acuteness of the attack has subsided and the patient is well on the road to recovery.

Amyloform.—For an antiseptic to be generally valuable it must possess rapid and permanent antimycotic properties; it must be easily miscible with oil and glycerine and its physical properties should permit its use as powder and as ointment. Cipriani (*Monatschft. f. prakt. Dermatolog.*, Oct. 15, 1900) is well pleased with the results he obtained with amyloform, a combination of starch with formalin, and prefers it to all similar drugs in incised abscesses, ulcers, wounds, burns and purulent otorrhea. Besides being perfectly harmless and free from any compromising odor, it remarkably hastens granulation and cicatrization.

On Typhoid Cystitis.—Despite the fact that in from 15 to 30 per cent. of all cases of typhoid fever, the specific bacilli are excreted through the urine, the occurrence of a cystitis is so rare that H. Curschmann (*Münch. med. Woch.*, Oct. 16, 1900) has seen but three cases. Cystitis is more liable to occur during the decline than during the height of the fever, and it is likely that the bacilli reach the bladder from the kidney, where they are filtered out of the blood. Clinically the subjective symptoms are remarkably slight, and a temperature elevation directly traceable to the cystitis was not observed. The urine appears similar to that in ordinary bladder inflammation, but, strange to say, is always acid in reaction when voided. Albumin is generally present, and as a rule there is but little difficulty in detecting the bacilli. The prognosis is fair, but the course is liable to be protracted. Internal drugs such as salol and uva ursi are generally all that is necessary and irrigations will be l rarely required. Some have found a specific in urotropin.

Methylene Blue in Dysentery.—The success which he obtained in gastralgia with methylene blue caused Berthier (*La Méd. moderne*, Oct. 10, 1900) to think that it might be of use in dysentery. The dominant symptoms of dysentery are strong desire to stool, frequent stools, colic, tenesmus, and an arrest of the biliary secretion due to a nervous disorder of the intestine. The writer says that methylene blue answers these indications as it is a parasiticide, aiming at the pathogenic cause of the dysentery; an analgesic, acting upon the nervous condition of the intestine manifested by the hyperexcitability of the large intestine; a cholagogue, having a very pronounced cholagogic effect in dysentery. Berthier was the first to use methylene blue in dysentery and he reports his first case in detail,

and states that he has had uniform success in a cases from the following method of treatment. The methylene blue is administered in warm injections of a liter, or of half a liter at first until the intestine becomes tolerant, containing in solution from one to two decigrams of the methylen. blue. Two to four injections are given daily. Until the patient has obtained a control sufficie to prevent accidents, four injections with two decigrams of blue are prescribed daily at hours such that the action of the drug extends over each two to four hours. Much care must be taken to favor tolerance of the injections. The patient should receive the injections as nearly as possible immediately after a stool, lying down with the reservoir a little elevated to facilitate the flow of the solution into the large intestine. After several injections the irritability of the hyperesthetic and intolerant intestine will be lessened. This result being due to topical action, the importance of repeating and prolonging the contact of the injection is understood; the patient should retain it as long as possible. There is no objection to more than four injections in twenty-four hours. Methylene blue is absorbed from the rectum very slightly. The urine becomes slightly bluish or greenish. Under the influence of the methylene blue the pains, colic, and tenesmus rapidly cease, and the desire to stool becomes less frequent. After one or two injections, or at latest on the second day, bile appears in the stools. This result appears to be due to the analgesic effect of the methylene blue. The writer thinks that the arrest of the biliary secretion in dysentery is due to a reflex action from the abnormal hyperexcitability of the large intestine. When the injections of methylene blue relieve this hyperexcitability, biliary secretion again becomes active. Methylene blue diminishes the virulence of bacteria, which are considered by some to be the cause of dysentery. It also indirectly lessens their virulence and toxicity by procuring the return of the biliary secretion, for the bile has undoubtedly an antiseptic and antitoxic action in the intestine. In those dysenteric patients who had gastric disturbance and vomiting, Berthier gave methylene blue by the mouth in doses of one to two decigrams with great success. The writer at the beginning of this treatment puts the patient on a milk diet and gradually adds eggs, meat, and rice. The patient's abdomen should be protected by flannel. Berthier believes that the simplicity of the treatment, its efficacy and the rapidity of its action, with the hasty disappearance of all symptoms, recommend methylene blue as the best treatment of dysentery.

Suppuration of the Parotid Gland.—H. P. Hamilton (*Western Med. Review*, Oct. 15, 1900) cites six cases illustrating the different pathological conditions causing suppuration of the parotid gland, discusses the pathology of each, and formulates the following conclusions: (1) Suppurations in the parotid gland may take place in any inflammatory disease. (2) Suppurations of the parotid gland are generally, if not always, due to septicemia. (3) Septicemia is not necessarily due to the so-called pyogenic germ. (4) Cases of mumps where the testicle is involved are always suffering from septicemia. (5) Nearly all patients with acute suppuration of this gland are delirious. (6) All can be relieved of this delirium in twenty-four hours by early incision. (7) Where suppuration exists in the parotid, death will probably follow if no incision be made to relieve same. (8) The incision should be made to include almost half the circumferences of the gland. (9) It is not necessary to curette more than is necessary to remove what pus comes into view, for suppuration invariably continues for several days thereafter. (10) When incision is made early the function of the gland is restored.

Dry Hot-Air Treatment in Private Practice.—R. H. Irish (*Albany Med. Annals*, Oct., 1900) gives his experience with a portable hot-air apparatus in private practice, and reports some cases which he treated successfully. In warm weather "local baths" may be given in the office, but in winter this is not advisable because of the danger of catching cold after the profuse general perspiration which always follows even the "local bath." In treating a limb or part it should be wrapped in several thicknesses of Turkish toweling, bony prominences being especially well covered. The temperature usually employed is 350° to 375° F., but it is best to begin with 250° to 275° F., as patients are usually nervous during the first treatment. The limb should be kept at the above temperature for 40 to 60 minutes. The temperature beneath the toweling around the limb is about 100° F. less than that in the oven. Massage and passive movements should be given immediately on removal from the oven of cases of stiff joints or adhesions of tendons. In other cases the part is dried with a coarse towel, rubbed with alcohol, and bandaged or wrapped in blankets for a while. The "general bath" is given by well wrapping up the patient in blankets and placing an arm or leg in the oven. Or, the patient may be placed in bed under a tent made of bed clothes into which the open end of the cylinder is introduced. Irish has found a temperature of 180° to 200° F. for one hour to be sufficient for the general bath, though it may safely be raised to 275° to 300° F., the head remaining out. After treatment the patient should be wrapped in blankets for an hour, then sponged with tepid water, dried, and rubbed with alcohol. The primary effect of this treatment is a sense of intense congestion so that the loose toweling seems a tight bandage and the limb seems intensely hot, almost burning. The skin is tense and dry, and almost scarlet. There is usually increased tension and frequency of the pulse and sometimes a throbbing headache. After fifteen minutes the congestion disappears and sweating, local and general, is profuse. The tension of the pulse becomes normal and pain is at once re-

lieved. There is almost a local anesthesia of the part treated and a feeling of well-being and drowsiness. Dryness of the mouth and intense thirst are frequent and drinking of water is allowed *ad libitum* during the bath. Sweating continues to the end of the bath, and if continued too long, at too high a temperature, or too frequently repeated, it may weaken the patient. On removal from the oven the tissues are relaxed, skin soft and moist, pain relieved, and all tenderness gone. Any swelling or edema formerly present is diminished or absent. Irish enumerates the conditions in which the hot-air treatment is indicated and the results to be expected from it in each. He does not consider hot air a "cure all," but simply a valuable adjunct to other treatment as indicated above.

Estivo-Autumnal Malaria.—Dr. Aristides Agramonte (*El Progreso Medico,* Nos. 8, 9 and 10) reviews the parasitology of paludism. He considers that besides the two varieties of the estivo-autumnal malarial parasites described by Marchiafava and Bignami, namely, the quotidian and the tertian or malignant, there exist other varieties of this parasite. Clinical observation in tropical countries shows the existence of a number of forms of very severe malarial disease and these take on types that depart considerably from the quotidian and tertian forms of the estivo-autumnal parasite thus far described. Laveran is the only authority now who considers that the various malarial parasites may be polymorphic forms of one and the same protozoan. Experience in warm countries points very clearly to the fact that the parasites of the various forms of malarial disease are distinct entities, and that they are never by any chance transformed one into the other. Dr. Agramonte has tried very hard to obtain some method of cultivating the malarial parasite outside of the human body. He now believes it impossible. He recalls the fact that Dr. Coronado of Havana claimed some years ago to have discovered a culture method for the parasite. His experiments were considered of sufficient value to deserve the encouragement of the French Orfila Prize in 1894. No one else has ever been able to confirm his results. During the autumn of last year and the spring of the present year Dr. Agramonte tried faithfully to follow the directions given by Dr. Coronado, but without success.

Absence of Saliva.—Dr. L. Quintin (*Revista Medico Dental* of Mexico, Sept., 1900) reports a case of asialism. The patient came complaining of not being able to swallow his food for want of saliva. His voice was husky and his mouth exhaled a nauseous odor. His teeth were covered by a thick coating of sordes. The patient's general health, however, seemed reasonably good except for a certain weakness, probably the result of the disinclination for food that had existed for some time. Inquiry showed that his urine was very much reduced in quantity. The patient presented some chronic eye trouble. For this it was ascertained he had been directed to use a solution of atropine. The case proved to be one of chronic atropinism. As soon as the atropine was stopped his condition began to improve, and at the end of the second week recovery was complete. The case seems a good illustration of the danger of allowing patients to have prescriptions renewed at will.

Pest Experience.—The conference on pest given by Professor Camillo Terni, Director of the Bacteriological Institute of Messina, before the Medical and Surgical Society of Rio Janeiro about the middle of the present year is reported (*Revista Medica de Sao Paulo,* Nos. 7, 8, 1900). The address contained an excellent review of the diagnosis, pathogenesis and prophylaxis of pest to date. Professor Terni concludes that the anti-pest vaccine of Haffkine provides the best conditions for the immunization of man and animals. The immunization thus acquired may last for a year, and may last even longer. The inconveniences claimed by some observers to occur after the use of this antipest vaccine are exaggerated and are not sufficient to constitute a contraindication to its employment.

"Puttee" Paralysis.—J. W. Springthorpe (*Intercolonial Med. Jour. of Australasia,* Sept. 20, 1900) reports the case of an officer who after an attack of enteric fever suffered from numbness, without actual pain, in the dorsum of both feet, followed by complete inability to raise the toes, and a partial inability to evert the feet. The right foot had recovered, but in walking the patient dropped and dragged the toes of the left foot. A great number of soldiers were similarly affected, and as the trouble seemed to be confined to those who had enteric fever, the condition was supposed to be a peripheral neuritis after enteric fever and was called "enteric feet." There was marked wasting of the tibial and peroneal muscles. The electrical reaction was normal, but weak. There was no tenderness on pressure over the nerves. The paralysis soon disappeared under faradism and massage. The trouble was confined to those muscles supplied by the peroneal nerve and its branches. This limitation of the condition suggested to the writer injury as its probable cause. It occurred to him that the puttees used by the soldiers might be the cause. The last few rounds of the puttees are fastened rather tightly directly over the head of the fibula, pressing the peroneal nerve against the bone, and the movements of the leg in marching increase this pressure. The writer thinks that this limited paralysis is due to the pressure of the puttees, and resembles "crutch paralysis." He was unable to ascertain whether this paralysis occurred only in those who had had enteric fever, but prefers to call it "puttee paralysis" rather than "enteric feet."

THERAPEUTIC HINTS.

To Relieve Vomiting.—Dr. Pepper's treatment for the vomiting of acute gastritis (*Therapist*, Oct., 1900) was one of the following prescriptions:

℞ Hydrarg. chlorid. mite 0.065 (gr. j)
Bism. subnitr..... 2.4 (gr. xxxvj)
M. Ft. Chart. xij. Sig.: Take one powder dry upon the tongue every three hours, until four or five have been taken.

℞ Acidi carbol. ..... 0.25 (gtt. iv)
Sodii bicarb. ..... 6.0 (ʒiss)
Elix. aurantii ..... 15.0 (ʒss)
Aquæ q. s. .....ad. 120.0 (ʒiv)
M. Sig.: A teaspoonful every three hours.

Stomach Pain.—To relieve pain in the stomach, especially that of hyperacidity, Van Valzah recommends the following:

℞ Codeine ..... 0.15 (gr. ¼)
Ext. belladon. ..... 0.08 (gr. ⅛)
Magnes. calcinat. ..... 2.0 (ʒss)

Chorea.—Avoidance of emotional disturbance, rest, for the most part in bed, a little chloral to induce sleep, frequent sponge-baths, gentle massage, and pleasant, quiet diversion will often work great improvement in a few days. The diet should be easily assimilated, nutritious, and contain plenty of fat in the form of cream and butter. Choreics are prone to crave indigestible articles. Tonics, especially iron, are indicated; arsenic is useful, but is harmful and rarely efficacious when pushed to its limit of toleration. Sometimes, however, a short vigorous course of arsenic acts favorably, beginning with a single drop and increasing one drop at a dose up to 10 or 15 drops three times a day for a child of seven years. In the severe cases absolute rest in bed, or in a padded corner on the floor, the free use of chloral or even morphine, hot baths and cold packs and feeding by nasal or rectal tube may be required. Strychnine helps to sustain the heart. Sulphonal, trional, exalgin, and antipyrin have given help in some cases. In the chorea of pregnancy it is not necessary to terminate gestation unless the motor storm is violent, the mental features pronounced, or the physical state low.—*Church and Peterson.*

Ichthyol in Acne.—As an external agent, writes Geo. T. Elliot, ichthyol in watery solution, 5 to 50 per cent., is most valuable. It is of special benefit in cases with much pustulation, and in full strength, or in a fifty-per-cent. dilution, it has commonly served the purpose of aborting a beginning lesion. In those cases of acne in which, from time to time, one or two papules begin to develop, ichthyol is a valuable agent in cutting short the career of these fresh lesions.—*Reference Handbook of the Medical Sciences, Vol. I.*

Purpura.—Simple purpura demands arsenic, first in moderate doses, then increased until beginning toxic effects. Iron perchloride, grams 2.0-4.0 (ʒss-j) daily, and if there is anemia, the inhalation of oxygen will promote hematosis. The disease requires fresh air in abundance and a generous diet. In peliosis rheumatica, in addition to the above measures, the salicylates may influence the joint affections. In purpura hemorrhagica much nourishment, by supporting the patient's power, is of the greatest service. Internally turpentine, acetate of lead, and dilute sulphuric acid are recommended, and the following:

℞ Fl. ext. ergotæ.....
Tinct. ferri chlorid.....aa 60.0 (ʒij)
Three to ten drops in water, three times a day, has proven useful in the author's cases. The management of secondary purpura is that of the diseases and conditions which it accompanies.—*J. M. Anders in "Practice of Medicine."*

Acupuncture in Lumbago.—In lumbago and similar myalgias, Sir James Grant inserts 12 or 14 small (No. 8) fine needles into the muscle through the skin for about one-half to three-quarters of an inch. He places them about the same distance apart, and leaves them in for one or two minutes. Although before puncture the painful muscles may be hard and tense, they soon relax and become soft, pliable, and painless. The patients, although previously disabled on account of the pain, can walk about freely when the needles are removed. After their removal the skin is sponged, and friction applied with a rough towel.—*Montreal Medical Journal.*

Mitral Stenosis.—When from neglect of precautions, from overtaxing the strength, from depressing emotions, or from the advance of the disease, decided symptoms of right ventricle failure supervene, such as great weakness, cough, dyspnea, with evidence of venous stasis in swollen jugulars and enlarged liver and dropsy, then use smart purgation by calomel or blue pill and colocynth, followed, if necessary, by salines. If the symptoms are urgent, venesection is of value; in certain cases no other treatment will take its place and avail to avert a speedy fatal termination. The indications are not a full, bounding pulse, but a small, weak, irregular pulse, many of the beats being scarcely perceptible. The heart will be beating violently, the apex beat almost imperceptible, epigastric pulsation marked, the liver enlarged, perhaps pulsating, and the jugulars full and pulsating. The contrast between the powerful right ventricle impulse and the small, weak pulse is very striking, and is one of the most important indications for venesection. This, with relief of the portal circulation by purgation, prepares the way for digitalis and like remedies, which without these measures afford no relief, and may indeed do harm. Digitalis should never be given for long at a time and its effect should be carefully watched.—*Sir W. H. Broadbent.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, NOVEMBER 17, 1900.

THE PLAGUE SITUATION AT SAN FRANCISCO.

The Medical News has commented from time to time on the fact of the presence of the Plague at San Francisco. Its persistence there calls for more active measures on the part of the local health authorities.

For the past eight or nine months at least plague has been present in that city, the secular and medical press to the contrary, and it would seem that had an energetic program been carried out, such as was done for the city of Glasgow, we would not have the uncomfortable situation outlined by Surgeon J. J. Kinyoun in the last Public Health Report, published in another column of this week's issue of the Medical News.

It has been steadfastly denied in some quarters that Plague has been present in the city, and the prophylactic measures, at one time adopted by the city health department, have ceased on the ground of lack of evidence and the difficulty in coping with the peculiar conditions prevalent in Chinatown.

The present outlook, according to Dr. Kinyoun, is that a more extensive outbreak is to be expected, and, if this is true, it is time that the health department of the city of San Francisco and the State of California should make more decided efforts at effectual sanitation.

POLYNEURITIS OF MALARIAL ORIGIN.

Most infections are primarily local, although they may extend by continuity or contiguity of structure and become widely or even generally disseminated through the blood-vessels or the lymphatics. The local disturbances result in part from the presence of the causative agents as foreign bodies, and in part from the biochemical reactions that take place between them and the cellular elements, while the constitutional disturbances, such as fever, headache, delirium, coma, are due to the absorption into the circulation of the toxic products resulting from the vital activity of the invading organism. These latter effects are generally expended upon the parenchymatous elements of the various viscera, and give rise to diverse aberrations of function, which sometimes will be found to be dependent upon alterations in structure, while at other times no lesion can be discovered with our present means of investigation.

The nervous system appears to be especially susceptible to influences of the kind under consideration, and during the last decade much has been added to our knowledge of the cerebral, spinal, and neural complications of the infectious diseases, and of the readiness with which the brain, cord, and peripheral nerves respond to toxic influences apart from infectious processes. Some of these poisonous substances appear to have a certain degree of selective affinity and to exert specific effects. Thus, the diphtheria toxin seems to attack by preference the palatal and other muscles and to cause paralysis; the tetanus toxin, to attack the motor apparatus and cause spasm; while all, in common, give rise to fever.

These reflections are applicable not alone to infections of vegetable origin, but likewise to those of animal origin, as, for instance, malarial fever and amebic dysentery, or of metabolic origin, as, for instance, the autointoxications, such as diabetes. In the malarial infections the plasmodia attack the red blood-cells, which they disorganize, and thus they induce anemia; in the spleen, in which they lodge, they give rise to hyperplasia; and the toxic products of their biological activity, it has been found, are capable of causing inflammation of nerves and presumably also of other parts of the nervous system.

The occurrence of peripheral neuritis as a complication of malarial fever has been reported from French, English, and American sources, and a case of more than ordinary interest is recorded by Baumstark (*Berliner klinische Woch-*

enschrift, 1900, No. 37, p. 815). The patient was a young man previously healthy, without a history of alcoholism or infectious diseases, in whom following an attack of malarial fever in the tropics, rapidly progressive paralysis developed in the lower extremities, with paresis in the upper, difficulty in swallowing, in speech and in the movements of the diaphragm, involuntary choreiform movements, and ataxia in the remaining voluntary movements of the upper extremities, abolition of the reflexes, especially the knee-jerks, derangement of sensibility, pain and tenderness in the muscles and the nerve-trunks, flaccid atrophy of the muscles, transitory incontinence of urine, quantitative and qualitative electrical changes, diaphoresis, and enlargement of the spleen.

There was no doubt of the existence of multiple peripheral neuritis, for which, in the absence of other etiologic factors, malarial fever was considered responsible, although malarial parasites were not found in the blood. The history, the gradual onset and invasion, the symmetrical distribution of the palsy in all four extremities, with predominant involvement of peripheral parts, especially in the perineal distribution, the pain and tenderness in muscles and nerves and the sensory changes, all negatived the diagnosis of anterior poliomyelitis. Further, the paralysis was confined to definite peripheral nerve-areas, rather than to muscles controlled by related groups of ganglion-cells in the anterior horns of the spinal cord. As against acute ascending paralysis were the onset with weakness in both upper and lower extremities simultaneously, the rapidly progressive development of the paralysis without actual extension, the favorable termination, and the sensory and electrical changes. Ewald (*Berliner klinische Wochenschrift,* 1900, No. 38, p. 845) also has reported a case of polyneuritis, occurring in a man, thirty-one years old, who had had an attack of malarial fever in the tropics and in whom there developed epigastric pain, with girdle-sense, paresthesia, anorexia, nausea, uncertainty, and, finally, loss of gait, impairment of memory, incontinence of urine, paresis and atrophy of the lower extremities, abolition of the knee-jerks, as well as of the cutaneous and periosteal reflexes, tenderness of the calves, indistinctness of speech, mental deficiency, enlargement of the spleen, unsteadiness in standing, sluggishness in the accommodative response of the pupils. Great improvement took place under appropriate treatment.

ECHOES AND NEWS.

NEW YORK.

Dr. Emmet and the Woman's Hospital.—It is reported that Dr. Thomas Addis Emmet has resigned from the staff of the Woman's Hospital. His successor has not yet been appointed. His son, Dr. J. D. Emmet, is temporarily acting.

New York Pathological Society.—At a regular meeting of this Society, held Wednesday, November 14th, Dr. E. M. Evans showed a case of congenital displacement of the heart; Dr. N. B. Potter reported a case of ruptured spleen from malaria, and Dr. O. H. Schultze one of hemorrhagic pancreatitis with fat necrosis and cyst of the stomach; Dr. Harlow Brooks presented the organs from a case of death by ether; Dr. Geo. P. Biggs showed specimens of tuberculous endometritis and tuberculosis of the bile-ducts; Dr. L. O. Conner reported cases of duodenal ulcer of embolic origin and carcinoma of the prostate; Dr. Herter contributed some remarks on diabetic coma.

Obituary.—Dr. Nathaniel P. Rice, an army surgeon in the Civil War, died of paralysis in a private sanitarium in this city on Saturday last. He was born in Cambridge, Mass., in 1828, and was graduated from Harvard with the famous class of '49. He studied medicine at the Harvard Medical School. At the outbreak of the Civil War he enlisted with a New York volunteer regiment. Two years later he was appointed a surgeon in the regular army. In 1864-65 he was medical director in Virginia and North Carolina. For a number of years he was in the bond department of the New York Custom House.

New York Hospital Fire Alarm.—Electricians at work Tuesday, November 13th, in Superintendent Ludlow's office, on the first floor of the New York Hospital, accidentally "crossed" the wire that connects the building with the Fire Department, and which is used for alarms in case of fire. The crossing closed the circuit and sent in an alarm to the Fire Department. Engine Company No. 14 and Hook and Ladder No. 3 came rushing around and found everything peaceful; nothing was known of the alarm at the hospital, until the firemen stopped in front of the building. Then the alarm was investigated and explained. There are 188 patients in the hospital, but fortunately none of them was frightened, and there was no excitement.

Warning Against Dog Bites.—Commissioner John B. Cosby of the Board of Health made the following statement this week:

"The Department of Health desires to call the attention of physicians and others to the occurrence of a number of cases of rabies among dogs throughout the city, and would request that whenever persons are bitten by strange dogs or

stray dogs they immediately consult a physician and have their wounds cauterized, and if then there is any question as to the existence of rabies in the animal communicate at once with the Department of Health."

Dr. Cosby said that there had lately come to the notice of the department several instances in which people bitten by dogs had neglected to have the wounds cauterized. He said that on Saturday a boy was bitten by a fox hound which, when examined, was found to have rabies. This dog, Dr. Cosby said, had bitten several other dogs if what he had heard was true.

State Veterinary College Burned.—The New York State Veterinary College building, which is a part of Cornell University, was partially destroyed by fire November 13th. The fire broke out on the third story, which is used as a laboratory by the veterinary and medical students, and the third story, together with valuable apparatus, was destroyed. The building was built by New York State for the veterinary department in 1895, at a cost of $60,000. The building also contained valuable laboratory apparatus and the Roswell P. Flower Library of Veterinary Science. It was constructed of white brick and was one of the handsomest buildings on the campus. The loss is estimated at $30,000, which will be covered by insurance. The library was saved, but was badly damaged by water.

Resident Students Wanted at Craig Colony.—The Craig Colony for Epileptics, at Sonyea, Livingston Co., N. Y., wants two recent graduates in medicine to serve six months, or a year, as resident students. The position is the same as that of medical interne in a general hospital. In addition to the unsurpassed opportunity for studying epilepsy (there are now 700 cases in the Colony), special opportunities exist for studying nervous and mental diseases and acquiring experience in general medical and surgical work. The incumbent receives board, lodging and washing, but no pay. Write to the Medical Superintendent, Dr. Wm. P. Spratling, at Sonyea, Livingston Co., N. Y., if further information is wanted.

New York State Medical Society.—The ninety-fifth annual session of the Medical Society of the State of New York will be held in Albany January 29, 30, 31, 1900. The meetings of the Society have always been replete in scientific work as becomes the representative society of the medical profession of the Empire State, and it is confidently expected that this meeting will equal those which have preceded it.

This circular letter is sent to every member of the Society with the request that those who desire to read papers will communicate at once with the Chairman of the Business Committee, Dr. Frank Van Fleet, 63 East 79th Street, New York City, or with the President, Dr. A. M. Phelps, 62 East 34th Street, giving the title of the paper and such other information as the author desires.

As there will be a great many papers offered, and the time necessarily limited, it is suggested that papers be condensed as much as possible in reading, as they can be published more fully in the Transactions. Arrangements for reduced fares can be made when purchasing railroad tickets.

The Craig Colony Prize (for 1901) for Original Research in Epilepsy.—Dr. Frederick Peterson, President of the Board of Managers of the Craig Colony for Epileptics, at Sonyea, N. Y., offers a prize of $200.00 for the best original unpublished contribution to the pathology and treatment of epilepsy. Originality is the main condition. All manuscript should be submitted in English. The prize is open to universal competition. Each essay must be accompanied by a sealed envelope, containing the name and address of the author and bearing upon the outside a motto or device, which is to be inscribed also upon the essay. All papers received will be submitted to a committee, consisting of three members of the New York Neurological Society, and the award will be made upon its recommendation at the annual meeting of the Board of Managers of the Craig Colony, October 8, 1901. Manuscripts should be sent to Dr. Frederick Peterson, 4 West 50th Street, New York City, on or before September 30, 1901. The successful essay becomes the property of the Craig Colony and will be published in its annual report.

Craig Colony Prize.—The following announcement is made:

New York, October 8, 1900.

To the President of the Board of Managers, Craig Colony, Sonyea, N. Y.

Sir:—Your committee of the Craig Colony Prize for Original Research in Epilepsy for the year 1900 begs to report that it cannot recommend that the prize be awarded. This verdict is a source of especial regret, as this committee arrived at the same conclusion in regard to the prize of 1899. This year but one essay was submitted.

In view of its failures, for two successive years, to recommend the awarding of the prize, your committee feels called upon to state what, in its opinion, is necessary for an essay to be considered deserving.

By the terms governing the competition, original research is a primary requisite. Research as to the pathological anatomy, the chemistry, the symptomatology, the causation, the treatment, or the nature of epilepsy, as to the position occupied by epilepsy in regard to social economics, or, in short, anything which will advance our knowledge of the disease, is what the prize calls for. It is, of course, necessary that the facts advanced be presented in a way to convince an unbiased critic of their accuracy, and that the

conclusions drawn be justified by the facts. No essay submitted either this year or last year has attained this standard. In view of the fertility of the field, of the constantly increasing number of investigators and of the present perfected facilities of research, your committee believes that the prize having failed to attract more meritorious contributions is to be explained by its not having been sufficiently called to the attention of original workers. It would recommend, therefore, that for the ensuing year no pains be spared to have the existence of the Craig Colony Prize made known to all qualified to compete for it.

Yours respectfully,

Geo. W. Jacoby, M.D.
Pearce Bailey, M.D.
Ira Van Gieson, M.D.

Loomis Sanitarium.—At the last meeting of the Board of Managers of the Loomis Sanitarium for Consumptives at Liberty Heights, Liberty, New York, it was decided that the time has now arrived to increase the charitable work in connection with the Institution, and that the present Sanitarium should be known as the Self-Supporting Division; the new plant to be erected to be known as the Charitable Division.

Ever since this Sanitarium was started, there have been a limited number of free patients provided for, and a few have always been carried at greatly reduced rates, but the managers have not been able to meet the great demand made upon them, by people of very limited or no means, for free treatment. It is their purpose, at first, to have the Charitable Division accommodate twenty-two patients, and the rates are not to exceed $5.00 a week *per capita;* this rate will include board, lodging, and medical attendance. They also guarantee to make a certain number of these original twenty-two beds free each year, and within five years to have the whole number free. Additions to the Charitable Division will, of course, be made from time to time, and the rates charged will in no instance exceed $5.00 a week, and as many free beds will be established each year as possible. The Charitable Division will be located about half a mile distant from the Self-supporting Division, but they will be managed under a single administration.

The Medical Board held its annual meeting a few days later and heartily endorsed the action of the managers, promising them all possible support in their worthy undertaking. At this meeting speeches were made by Dr. Henry F. Walker, Dr. Daniel Stimson, Dr. H. P. Loomis, Dr. Chas. E. Quimby, Dr. Frank Miller, and Dr. J. Edward Stubbert, all of whom expressed the opinion that the enlargement of this Charitable Division was not only a worthy provision, but an immediate and urgent necessity, and they believe its growth will be even more rapid than has been that of the Self-supporting Division during the four years of its life. During that time, this Sanitarium has grown from five to twenty-one buildings and from a capacity of twelve to one hundred and twenty-five patients, and it is still growing. It seemed to be the united opinion that the method of working a Self-supporting and Charitable Division under one administration, whereby the surplus income from the one could be utilized toward the support of the other, is an ideal way of administering charity upon a solid and sound basis.

New York State Conference of Charities.—This Conference, designed to meet annually in this State, has been inaugurated for the consideration of questions of practical importance with relation to the public and the private charitable and correctional work of the State, with the hope that the Conference will be able to exert a powerful force for good in securing intelligent action upon such questions. Conferences similar in purpose have for some time been organized and carried on in many of the States, principally in the West, and those who are well informed on the subject regard them as sources of beneficent influence. All who are officially connected with public or private charitable or correctional work in New York State, or who take an active interest therein, are invited to enroll themselves as members of the Conference and to attend its sessions. There are no other tests of membership, and no membership fee is charged, the expenses of the Conference being met by voluntary contributions. The Conference meets at the Capitol in Albany Tuesday, Wednesday and Thursday, November 20, 21, 22, 1900. On the opening day addresses will be delivered by Hons. W. R. Stewart, J. H. Blessing, Bird S. Coler, William P. Letchworth and Rev. T. A. Hendrick. On Wednesday papers will be ready as follows: "Need and Value of Settlement Work," by J. B. Reynolds; "The Breaking Up of Families," by E. T. Devine; "Classification of Destitutes," by Hon. A. Goetting; "A Model Institution," by D. Delehanty; "New York's System of Caring for Destitute," by Homer Folks; "Causes of Children Becoming Charges," by Dr. W. O. Stillman. On Thursday the following papers will be read: "Duty of State to Idiotic and Feeble-Minded," by Dr. J. F. Fitzgerald; "Cooperation in Hospitals for the Insane," by Hon. P. M. Wise; "New York's Prison System," by H. G. McLaughlin, and "Houses of Refuge for Women," by Mrs. C. L. Lowell.

Free Pasteur Treatment.—President Murphy of the Health Board has announced that no new cases of hydrophobia have been recorded recently, but he is reported to have said that he is confident that the notice to the effect that the Health Department would care for all cases free of charge would bear good fruit. "Only a week or two ago," said President Murphy, "we sent out a notice to all physicians that we were prepared to treat hydrophobia cases at the Willard Parker Hospital. We have been prepared to do that for two years, but the public didn't know it.

We think the city ought to care for patients suffering with rabies and for people who have been bitten by dogs."

The notice sent by the department to physicians said that treatment for the prevention of rabies, according to the method of Pasteur, would be administered free to any person residing in Greater New York; that it would be administered on request to persons outside the city upon the payment of $50 for the virus used, and that to persons unable to pay that fee treatment might be administered without charge by direction of the Board of Health.

Wesley M. Carpenter Lecture.—This lecture was given by Dr. James Ewing, Thursday, November 15th, at the Academy of Medicine, on "Conjugation in the Asexual Cycle of the Malarial Parasite." He said: "The evidence which favors the belief in conjugation of the amœboid forms of the tertian parasite consists in the observation of several cases, showing two broods of parasites, one of which was very young, the parasites being very often twinned, and the other full-grown and invariably single. In one case the young brood of twins was found to be succeeded by a later brood, all single. By the application of Nocht's stain all stages of the union, first of the bodies, later of the two or three chromatin masses present in the conjugating parasites, were observed. Several possible objections to the theory of conjugation were considered, including the doubtful significance of multiple chromatin grains in young parasites, and the possibility that one of the twins may be destroyed and extruded, while the other goes on alone to full development. Conjugating forms are usually scarce and difficult to find except in rich infections and in initial or second paroxysms.

The speaker suggested that the tendency toward spontaneous disappearance of malarial infection in the human subject may be referable to exhaustion of the power of reproduction by conjugation and the necessary development of bisexual forms which in the human host are sterile.

The conjugating parasites were usually found to suffer in appearance. One presents the ordinary thin ring form of the young tertian organism, while the other is coarser, and may not assume the ring form, or, if it does so, the ring incloses little hemoglobin. The coarse ring appears to develop, when not conjugating, into a compact, densely-staining body with six nuclei, and resembles the flagellating body seen in shed blood which has been kept moist for 15 or 20 minutes. It probably does not flagellate in the circulating blood, but reaches the stage of subdivision of chromatin granules, and is capable of developing the microgametes, or fertilizing flagella, of the bisexual cycle, which is completed in the mosquito. The thin ring form developing singly produces a body which resembles the macrogametocyte of shed blood. Both these forms in their full development in circulating blood resemble the microgametocytes and macrogametocytes described by Bastianelli and Bignami in the mosquito stomach and also traced by them, indistinctly, in the circulating human blood. The author considered the biological significance of conjugation among related protozoa, finding abundant field for this method of reproduction in the malarial parasite. Among related protozoa reproduction by conjugation of individuals not fully differentiated into sexes serves as a method of multiplication for three or four generations, after which this method is incapable of developing new individuals, and another, bisexual, method of reproduction is rendered necessary, usually associated with a completely new phase of existence in a new host. The full significance of the process was claimed for malarial conjugation, and it was not to be regarded as a form of embryonal cohesion as described by Pfeiffer and illustrated in many gregarines.

The single and the conjugating cycles of the tertian parasite were illustrated by colored lantern slides.

Transfer of Criminal Insane.—The first transfer of insane convicts from the Matteawan State Hospital to the new hospital at Dannemora, Clinton County, was made last Wednesday, when forty-eight male patients were sent from Matteawan by rail in charge of attendants. Within a month another transfer will be made to bring the total population of the new institution up to 150, which is its present capacity.

PHILADELPHIA.

German Hospital.—The new dormitories at this hospital have been formally taken possession of by the employees. The dormitories were built because the crowded condition of the hospital rendered necessary the use of the attachés' rooms for the care of patients.

Dr. Yglesias.—Dr. Manuel S. Yglesias, Health Officer of Vera Cruz, Mexico, was recently in this city. While here he made an inspection of the State Quarantine Station at Marcus Hook in order to familiarize himself with the methods there used.

Inspection of Dairies.—Col. J. Lewis Good, Chief of the Bureau of Health, and Drs. Abbott and Stewart, bacteriologists, are making a tour of inspection of the various dairies which furnish the bulk of Philadelphia's milk supply.

Sanatorium Incorporated.—Articles of incorporation have been filed by the Pennsylvania Sanatorium Company, with a capital stock of $50,000. The object of the corporation is to treat consumptives and an institution for that purpose will be built at Clifton Heights, a suburb of this city.

An Honored Guest.—Dr. Tilmann, Professor of Surgery in the University of Greifswald, Germany, visited this city recently as the guest of Prof. W. W. Keen and operated in the latter's clinic at the Jefferson Hospital. A reception to Dr. Tilmann at the University Club was attended by the prominent surgeons of the city.

Medical Aid Association.—The Mutual Aid Association of the Philadelphia County Medical Society held its annual meeting November 12th. The Association has been in existence for twenty-two years. Aid is extended to widows and orphans of members and also to members themselves if long illness or accident render this necessary. The Association is one of the residuary legatees of the estate of the late Dr. Albert Frické.

Preliminary Education of Medical Students.—An interesting compilation of the register of new students at the University of Pennsylvania has been made with reference to previous educational institutions attended. The list shows that 71 per cent. of the medical freshmen have matriculated at some college or university. In the law department 57 per cent. are from colleges, while in the dental department only 15 per cent. are college men. The above figures are highly gratifying to the medical profession.

Philadelphia Hospital.—Dr. David Riesman reports a case of abscess of the liver in a male patient, with operation and recovery. Aspiration was made and this was afterward followed by operation. The transpleural route was chosen, no serious results occurring from the pneumothorax thus caused. Three quarts of chocolate-colored fluid, which proved to be sterile, was evacuated. Regarding the diagnosis of single abscess of the liver, great stress was laid upon the shape of the abdomen. This is a peculiar flattened-cylinder appearance which is not seen in other conditions.

Druggists' Grievances.—A few more of the druggists have paid their fines for failing to display their licenses properly, others have appealed their cases. A large number of the prosecutions have been dropped by an agreement between the State Pharmaceutical Board and the Retail Druggists' Association. The latter is to introduce a bill in the State Legislature to abolish the law requiring a registration and payment of $3.00 every three years.

A Record for Dislocations.—A young man, twenty-six years of age, was lately treated at one of the city hospitals for dislocation of the left shoulder. The patient stated that this was the thirty-eighth time the shoulder had been dislocated. The man was formerly a traveling salesman and has been treated by many of the prominent surgeons of the country. The joint is very easily dislocated, but the reduction is always difficult, ether having been given during twenty-eight of the reductions. The patient refuses operative procedure which, it is believed, would prevent future dislocations.

Newspaper and Medical Items.—It is a well-known fact that the daily papers often give glowing and distorted accounts of some case or of surgical operations. Some physicians have been strongly suspected of encouraging newspaper mention of their doings, but it is hardly necessary to state that reputable practitioners discountenance it. Dr. W. W. Keen has recently made an effort to stop all press reports of his clinics and it is to be hoped that all the surgeons of the city will organize and take a determined stand in the matter. One of the city papers has continued to print reports of impossible clinics after being courteously requested by Dr. Keen not to do so. A move in the right direction has been made and the profession should see that such demands are complied with.

CHICAGO.

Polish Hospital.—A hospital to cost $250,000 is to be erected by the Sisters of the Holy Family of Nazareth in this city. It will occupy an entire block, will be constructed of cut stone and pressed brick, will be equipped with all modern appliances and ready for occupancy some time in October, 1901.

Medical Inspection of Schools.—As a means of keeping the expenditures of the Department of Medical Inspection within the appropriation for its maintenance, the Board of Education of Chicago has ordered that the general medical inspection of the schools be discontinued for the remainder of the calendar year. In its place a new system, which will greatly curtail the expense, has been inaugurated. Ten of the original fifty inspectors will be retained and an emergency corps established in each division.

Chicago's Paris Medal in Pawn.—If Chicago can raise 600 francs ($120) it can secure a gold medal for the exhibition of the City Health Department at the Paris Exposition. The medal has come C. O. D. and is held by Columbia University. Commissioner Reynolds was notified yesterday that the gold medal award had reached New York and was held by the authorities of Columbia University pending the delivery of the money.

Freed from the Grip of Quacks.—When enough of the country papers show the good sense and backbone which is very manifest in the office of the *Brown County Herald*, published at Hiawatha, Kan., the clause in the advertising contracts of the nostrum makers which virtually compels the papers to oppose any legislation which is for the good of the community by being inimical to the nostrums will lose its power. The *Brown County Herald*, in a recent number, said:

We have at last done what we have wanted to do for many years—we have thrown out of this paper every advertisement that can be by any chance considered objectionable in any de-

gree. And hereafter we shall print no offensive advertisements. We have an idea that every advertisement is read, and this being so, we don't want any one to read or to put any faith in the cure-alls and nasty nostrums that are always conspicuous advertisements in every possible newspaper in every possible public place in America. If persons are ailing, they should not hesitate to consult a reputable physician. Another thing: From this time on we will not print advertisements of traveling quack doctors. We want clean advertising matter, or else we want none. This means a loss to us of not less than $800 a year.

We believe that the people who have glanced at —— —— offensive propositions, and at —— ——, —— ——*et al.*, including the bids of various quack doctors to cure weak and suffering men and women, will miss them in this paper with not a little pleasure. It makes no difference what ails you, don't be afraid to tell an honorable physician about it, and submit to his advice and treatment.

Beware of quack doctors.

Don't read filthy ads.

Don't buy quack medicines.

Don't have anything to do with strange doctors. They are generally disreputable, and entirely unable to do any more for you than to mercilessly take your money.—*Drug Circular.*

Testimonial Banquet to Dr. Christian Fenger.—A testimonial banquet was tendered to Dr. Christian Fenger at the Auditorium Hotel, Chicago, November 3, 1900. It was a representative gathering, there being over five hundred physicians present from all parts of the United States. The meeting was called to order by Dr. J. B. Murphy, who introduced as toastmaster Dr. Charles A. L. Reed of Cincinnati, Ohio, President of the American Medical Association. Dr. George N. Kreider of Springfield, Illinois, and Dr. William A. Evans of Chicago read letters and messages of regret from the officers of various State, County and local medical societies in the East, West, North and South. Dr. W. W. Keen of Philadelphia presented the loving-cup to Dr. Fenger. One side of the cup bore the inscription:

> "This great good man for noblest cause displays,
> What many labors taught, and many days."

On the other side is inscribed: "To Dr. Christian Fenger, on the sixtieth anniversary of his birth, from those who know and love him best—The Medical Profession." Dr. Fenger accepted the loving-cup in a brief but felicitous speech. Toasts were responded to as follows: "The Physician as a Leader of Men," by Dr. Edwin Ricketts of Cincinnati, Ohio; "The Physician in Times of Plenty," by Dr. W. H. Earles of Milwaukee, Wisconsin; "The Physician in Times of Adversity," by Dr. J. M. Mathews of Louisville, Kentucky; "The Physician as a Scientist," by Dr. N. Senn of Chicago, Illinois; "The Physician as a Good Fellow," by Dr. C. A. Wheaton of St. Paul, Minnesota; "The Physician in Times of War," by Dr. C. B. Nancrede of Ann Arbor, Michigan; "The Physician in Times of Peace," by Dr. William E. Quine of Chicago, Illinois; "The Period of Awakening and the Period of Progress," by Dr. Christian Fenger of Chicago, Illinois. Dr. G. Frank Lydston of Chicago recited in an admirable manner a humorous but eulogistic poem, written in Hoosier dialect, on Dr. Fenger. Dr. L. H. Watson of Chicago likewise paid a tribute to the illustrious guest in a poem. Dr. C. Lange of New York City and Dr. Victor C. Vaughan of Ann Arbor, Michigan, made brief speeches, in which they eulogized Dr. Fenger.

GENERAL.

Plague in Mauritius.—Fifty fresh cases of bubonic plague occurred on the Island of Mauritius last week. Thirty-four deaths have resulted from the disease.

Smallpox Epidemic in Paris.—An epidemic of smallpox has broken out in Paris, due probably to the massing of Arabs and other people from the East during the exhibition. Notices have been posted by the police warning persons who have not been vaccinated within six years to be vaccinated now. Every precaution to stamp out the disease has been taken.

Obituary.—Dr. W. M. Ansell, a prominent physician of Cleveland, Ohio, died recently at the residence of M. O. Waggoner, in Toledo. The cause of death was heart disease.

Dr. Robert B. Brown died November 13th at his home in Phillipsburg, N. J., of heart trouble, at the age of seventy-six. In the Civil War he was a sergeant in the Union Army and for several years afterward was stationed at Galveston, in charge of work for the Government. One daughter survives him.

St. Louis Medical Society of Missouri.—The program of the meeting of Saturday, November 10, 1900, of the Society included the following papers: "Report of a Case of Malignant Icterus," by Dr. T. A. Martin; "Two Recent Cases of Pelvic Surgery with a Criticism of Prevailing Methods of Drainage," by Dr. G. Wiley Broome.

Unnecessary Taxation.—The Medical News calls the attention of its readers to the following letter: At the last meeting of the Congress of American Physicians and Surgeons we were appointed a committee with full powers to urge upon the Congress of the United States the repeal of those provisions of the War Revenue Act of 1898 which lay a tax on legacies to educational, charitable and religious organizations.

A petition has been introduced into the Senate by Senator Lodge, and a copy is in the hands of the Hon. Sereno Payne, Chairman of the Committee on Ways and Means of the House.

Will you not exert your utmost influence with any members of the Congress of the United

States whom you can address personally or by letter on the subject of such appeal?

The revenues of the government are admittedly unnecessarily large and commercial interests will not be idle.

Hoping that we can count on your active interest in this matter, we remain,

Yours very truly,

Fred'k C. Shattuck.
Abraham Jacobi.
William H. Welch.

Yellow Fever in Havana.—Surgeon A. H. Glennan, Chief Quarantine Officer for the Island of Cuba, has made a report to the Treasury Department on the yellow-fever situation in Havana. He says that the number of cases decreased in the last week of October and that there were only thirteen deaths in that week. He quotes Major W. C. Gorgas, U. S. A., Chief Sanitary Officer, as saying that, notwithstanding the general distribution of the disease, infecting localities not heretofore infected, and the large number of people attacked, an epidemic condition does not exist and that such a situation in Havana is impossible. He says that from June 1st to October 19th there were 789 cases officially recorded; that the official maps of the city show that there are 857 square blocks in the city, and that of this number 525 square blocks have had no cases at all. "The acceptation of the term as it is generally understood in the United States and as applied to epidemics in our great cities," he says, "certainly show no epidemic here at the present time." In a population of 242,000 the average in Havana in October was ten new cases of yellow fever a day.

Plague at San Francisco.—Official reports show that two additional cases of the plague were confirmed on November 2d.

Yellow Fever at Natchez.—One case of yellow fever was reported from Natchez, Miss., November 6th.

Surgeon-General Sternberg's Report.—In his general remarks on the gunshot wounds of 1898 and 1899 the Surgeon-General says: Of the 4919 men injured by gunshot during the years 1898 and 1899, 586 were killed and 4333 were wounded and received into the field and other hospitals. The killed constituted 11.9 per cent. of those struck; the wounded 88.1 per cent. In other words, 1 man was killed for every 7.4 wounded. The Mauser bullet must, therefore, be regarded as less deadly than the larger missile used during the Civil War. The Medical and Surgical History of the Civil War shows the following casualties:

	Killed.	Wounded.
United States troops.....	59,860	280,040
Confederate troops.....	51,425	227,871
Total	111,285	507,911

In percentages the casualties were: Killed 17.97; wounded 82.03, or 1 man killed to every 4.56 wounded. The relative proportion of killed was therefore considerably larger during the Civil War than during our recent experiences. It is to be noted also that many of the wounds of the past two years were made by missiles of large caliber. Of those reported in 1899, 471 were specially stated as having been caused by the Remington bullet of caliber .45. It is safe to say that had the whole number of wounds received been inflicted by the smaller Mauser or Krag-Jorgensen bullet the percentage of immediately fatal wounds would have been materially lessened.

The less deadly character of the injuries inflicted by the modern bullet is manifested also when we exclude the killed and regard only those wounds which came under the care of the surgeons. Of these, during the two years, there were 4333, and 259 of the patients, or 6 per cent. of the whole number, died. The corresponding percentage from the records of the Civil War was 14.3. Table C in Part I. of the Medical Volume of the Medical and Surgical History of the War of the Rebellion shows that among the white troops of the Army there were borne on the reports of sick and wounded 230,018 gunshot wounds, of which 32,907 or 14.3 per cent. proved fatal. The marked reduction of the ratio of killed to wounded may be placed to the credit of the small caliber bullet; but the lessened mortality among the cases which came into hospital may not wholly be attributed to the humane character of the wounds inflicted by this missile. Due credit must be given to the improved surgical methods of the present day. Wounds of any region of the body may be taken in comparison and the result will always be found to show a decided lessening in the percentage of cases ending fatally among those of the past two years as compared with those of the Civil War. Take, for instance, gunshot wounds of the femur. During the Civil War surgeons in the field hospitals regarded a fractured femur as a serious menace to life, the danger from which was believed to be materially lessened by an immediate amputation. The field hospital surgical work after a battle consisted in great part of amputations, excisions and resections. Of 6576 fractures of the femur 2923 cases were treated by primary amputation, 186 by resection and the remaining 3467 by conservative or expectant measures; this conservative action being due in many cases to a want of favorable conditions for the performance of primary operations. The limb was promptly amputated in 44.4 per cent. of these gunshot fractures. On the other hand, during the past two years 82 cases of gunshot fracture of the femur were reported, 6 of which were treated by primary amputation and 2 by resection, the remaining 74 cases being treated by conservative methods, not because the conditions were not favorable for the performance of primary operations, but because of a conviction that under present methods of treatment the limb could be preserved without adding materially to the danger to life. The

limb was lost through surgical intervention in only 7.3 per cent. of the cases.

Not only limbs but lives were saved by the surgical practice of the past two years. In the 82 gunshot fractures of the femur the upper third was involved in 32, of which 5 were fatal; the middle third in 27, of which 3 were fatal; and the lower third in 23, of which 1 was fatal. The mortality varied from 4.3 per cent. of the cases in which the lower third was fractured to 15.6 per cent. of the cases in which the upper third was the site of the injury, whereas the corresponding percentages of fatal cases during the Civil War were respectively 42.8 and 49.7. The whole of the lessened mortality in these serious fractures may be credited to the protection given to the wound by the first-aid dressing and to the care exercised in the subsequent aseptic treatment of the fractured limb.

In penetrating wounds of the thorax the rate of mortality fell from 62.6 per cent. during the Civil War to 27.8 per cent. during the years 1898 and 1899. The Civil War reports show 8403 cases in which the results were determined; 5260 deaths occurred among the number. The reports for the later years, as already stated, show 198 cases of which 55 were fatal.

There were during the Civil War 3475 penetrating wounds of the abdomen in which the ultimate results were determined; 3031 of these, or 87.2 per cent. of the total, proved fatal. During the years 1898 and 1899 116 cases, 81 fatal, were recorded, the fatal cases constituting 70 per cent. of the total. Of 10 cases in which laparotomy was performed 9 were fatal.

The alteration in the percentages of mortality in fractures of the cranium is less marked than in wounds of other parts of the body. Of 4243 cases of cranial fracture during the Civil War, 2514 or 59.2 per cent. were fatal. In 1898 and 1899 68 cases were recorded with 37 deaths, the latter forming 54.4 per cent. of the whole number.

Suicides in the Army. — Surgeon-General Sternberg has prepared statistics making a comparison of cases of suicide and homicide which occurred in the army during the years of 1898 and 1899 compared with the ten years between 1888 and 1897. It shows that there were relatively fewer homicides during those two years than during the previous decade. The average number of suicides per year in an army of 27,116 for the ten years was 17. The ratio per thousand was .63 per cent. The strength of the army in 1898 is given at 147,795, the average number of suicides 38, and the percentage per thousand .26. The strength of the army in 1899 is given at 105,546, and the number of suicides at 30; ratio per thousand .28 per cent. During the ten years from 1888 to 1897, the homicides are given at 5.5 per cent., and the ratio per thousand .20 per cent. For 1898 the number of homicides at 19, and the ratio per thousand .13 per cent.; for 1899, the number of homicides at 23, and the ratio per thousand .22 per cent.

OBITUARY.

DR. HENRY D. NOYES, M.D.

New York loses by the death of Dr. Noyes one of its most noted specialists. This city can claim him as one of her own, as he was born here in 1832 and has been connected with medical work in the city ever since his graduation from the College of Physicians and Surgeons in 1855 to the time of his death, which took place at his summer residence in Mount Washington, Mass., November 12th, of pneumonia. After graduation he spent four years on the Continent, where he devoted the major portion of his post-graduate study to the eye and the ear, in which

Dr. Henry D. Noyes, M.D.

branches he has since shown such a marked proficiency.

Dr. Noyes was the type of specialist that medicine is proudest of, thorough and painstaking in all of his work, brilliantly equipped intellectually and possessed of deft operative ability. His teaching was incisive and definite and his students always carried with them some practical information after his lectures. His contributions to the literature of eye disease have been many, and his text-book on "Diseases of the Eye" has been standard for many years.

Dr. Noyes was visiting surgeon to the New York Eye and Ear Infirmary and was a member of the Academy of Medicine, its Ophthalmic Section and the American Ophthalmological Society. His local interests were with the County and State Medical Societies. He was a very busy man, but found time for a number of out-

side interests, and was frequently to be found at the Century Association, of which he was a member, at its noted gatherings. He was also a member of the Nineteenth Century Club, and the New England Society. Dr. Noyes is survived by his widow, two daughters, and one son, the latter a senior at Yale.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, November 7, 1900.

THE PLAGUE AT GLASGOW AND CARDIFF—ALL DANGER OF EXTENSION PASSED — PLAGUE AT MAURITIUS AND HONG-KONG—THE OPEN-AIR TREATMENT OF CONSUMPTION—PROGRESS OF THE MOVEMENT—CONFERENCE IN LONDON OF THE POOR-LAW AUTHORITIES TO CONSIDER THE ESTABLISHMENT OF SANATORIA—OPENING OF A SANATORIUM FOR LIVERPOOL—DEATH OF SIR HENRY ACLAND, BART., LATE REGIUS PROFESSOR OF MEDICINE AT OXFORD—HIS WORK AT OXFORD UNDER ECCLESIASTICAL OPPOSITION TO SCIENCE.

Much satisfaction is felt in Glasgow at the official announcement that 6 of the plague patients have been dismissed cured. There are now only 14 cases in hospital and no fresh ones have occurred since my last letter. In consequence of the apprehension aroused in foreign governments by the fatal case of plague at Cardiff of which I have informed you, the authorities addressed an important letter to every Consul at the port, pointing out the prompt measures taken to deal with the case, to dispose of the man's body, and to prevent the spread of the disease. It is also pointed out that the period of incubation has been passed by many days and that there is no probability of any fresh case occurring. It is thought that the man who died was infected by fleas that lived on rats which were afterward found dead in the vessel on which he sailed. The nurse who attended the man was isolated with him, and after the latter's death was kept isolated. She is now considered so far out of danger that she is nursing ordinary patients.

According to a telegram received at the Colonial Office, 33 fresh cases of plague, of which 26 were fatal, occurred at Mauritius during the week ending October 11th. The total deaths from plague were 32. For the week ending October 15th, 4 cases of plague and 4 deaths occurred in Hong-Kong.

The movement to establish sanatoria for the open-air treatment of phthisis continues to progress. For some months the Board of the large metropolitan districts of Poplar and Stepney has been considering the subject. It is of the opinion that by the proper treatment of the disease in its early stages much benefit and in some cases cure would result. After a conference with the medical officers and clerks of the Unions of the district a deputation was appointed to wait on the Government authorities—the local Government Board. The latter expressed its sympathy with the desire to provide the accommodation referred to, but objected to individual action in the matter, the question being in the Board's opinion a metropolitan rather than a local one. Adopting this suggestion, a conference of all the Poor-Law authorities in London will be held at St. Martin's Town Hall to consider the question of establishing hospitals for the open-air treatment of consumption. The great northern city of Liverpool is building a sanatorium for the open-air treatment in the forest of Delamere, 500 feet above the sea level. It has been enabled to do this early by reason of the munificence of two of its citizens, who each have given £7500 for the provision of the necessary buildings. The position is an ideal one. It is sheltered from the east winds by a ridge of hills and overlooks a richly-wooded, undulating country toward the Mersey and the still more distant Welsh hills. It will be further improved when the 3000 pine trees, the gift of another citizen, have grown up. They will serve the treble object of beautifying the site, protecting the buildings and giving the air that peculiar hygienic character which is so valued. The foundation stone was laid by Lord Derby who showed such a grasp of the subject that Sir William Banks, the distinguished Liverpool surgeon, paid him the high compliment of saying that his description of tuberculosis and his treatment was such that a professor of medicine might envy. His alliteration of "dust, dirt, and darkness" as the media in which the disease thrives was particularly happy, as was also his statement that by the New Gospel consumption had been transferred from the category of hereditary to infectious diseases and had had its true method of treatment indicated.

The death of Sir Henry Acland, Bart., late Regius Professor of Medicine in the University of Oxford, and the friend of Ruskin, removes a distinguished, highly-cultured physician from the profession. He was descended from an old Saxon family of Devonshire squires and was educated at Harrow and Christ Church, Oxford, taking the Bachelor's degree in the University in 1840. He then proceeded to study medicine in St. George's Hospital where Sir Benjamin Brodie was a surgeon. In 1843 he went to Edinburgh and studied there for a year or two under Dr. Alison. In 1844 he was awarded a gold medal for an essay on "Feigned Insanity," which was considered a valuable contribution to a subject then little known. In 1845 he was appointed to the Lee Readership in Anatomy in the University of Oxford and commenced the formation of an extensive collection of physiological specimens. In 1847 he was appointed physician to the

Radcliffe Infirmary, Oxford, a post which he held for forty years. In 1847 he was elected a Fellow of the Royal Society at the early age of thirty-two. In 1857 he was appointed Regius Professor of Anatomy in the University of Oxford. He then applied himself to the formation of the pathological collection in the museum. His work at Oxford in those days was performed in the face of great obstacles. Natural science was not only almost ignored, but regarded by many religious leaders as tending toward infidelity. The whole spirit of Oxford was classical and ecclesiastical. When it was proposed to set up a new scientific museum there was a cry of dismay and a tempest of opposition. Every vote in convocation was carried only by a narrow majority. The grant for the lighting of the court of the museum was carried, but that for the burners was lost! Describing the condition of medicine in his student days, Sir Henry Acland wrote: "Any place was thought good enough for a medical student. The neglect of him by governments was a proverb. What was the result? A surgeon of note was shown to me as the one man strong enough to carry away a body under each arm from the graveyard for the body-snatchers." Acland as a teacher exerted a wide influence on many generations of students for which, and not for any discoveries or original work, will he be remembered. He infused into his labors a moral earnestness, a dignified devotion and sincerity which were a standing influence of the best kind. One of his most serviceable pieces of work was a memoir on the visitation of cholera in Oxford in 1854. He showed that it was full of the filthiest cesspools, contaminated wells, badly constructed drains, and sewers, and that the narrow streams about the town were befouled by the drains. It was, therefore, an excellent center for an epidemic. Attacks occurred previously in 1832 and 1849, but they were regarded as visitations from God and were never investigated scientifically. His work led to great sanitary reform which afforded a lesson for the whole country. His most important publication was a volume on "National Health," written in 1871. It deals extensively with the essentials of public health as then understood. His "constitutional English serenity in danger" is illustrated by the following story told of him by John Ruskin. At the age of thirty he was wrecked in a steamer on the Dorset coast. The steamer laid wedged in the rocks all night and the dawn broke on half a mile of dangerous surf between the ship and the shore—the officers in anxious debate, the crew in confusion, the passengers in hysterics or at prayers, were all astonished and many were scandalized at the appearance of Dr. Acland from the saloon in punctilious morning dress with the announcement, "Breakfast is ready." To the impatient clamor of indignation with which his unsympathetic conduct was greeted, he replied by pointing out that no boat could go on shore, far less come from it, and that in the meantime, as most of them were wet and cold and at the best must be dragged ashore through the surf or else swim for their lives, they would be extremely prudent to begin the day as usual with breakfast. The hysterics ceased, the confusion calmed, what wits anybody had became available again, and not a life was ultimately lost. Sir Henry Acland had a long and intimate connection with the Royal Family. He was appointed a member of the Prince of Wales' suite when he visited Canada and the United States in 1860. When the Prince was at Oxford he was appointed his honorary physician.

TRANSACTIONS OF FOREIGN SOCIETIES.

CHOLELITHIASIS — URETHRAL CALCULI — VESICO-VAGINAL FISTULAE—XIPHOPAGUS MONSTER—PLAGUE IN JAPAN—RAW MEAT AND TUBERCULOSIS—TRYPANOSOMES OF RATS—PERIODIC SEXUAL EXCITEMENT IN GENERAL PARALYSIS—CEREBROSPINAL FLUID IN MENINGITIS—BACILLUS TYPHOSIS AND ITS TOXINS—TUBERCULOSIS IN TUNIS—BACILLUS DIPHTHERIAE AND AGGLUTINATION—PECULIAR FORMS OF VARICELLA—TYPHOID PLEURISY—TYPHOID PULMONARY INFARCT.

Lejars at the Société de Chirurgie de Paris, October 3, 1900, in behalf of Sierra (Santiago de Chili) described the latter's method of dealing with cholelithiasis. First, a cholecystectomy is done, the necessity for which in the opinion of the speaker is not always indisputable; second, a choledochotomy is performed followed by exploration and suture of the canal and finally free drainage of the abdominal wound for forty-eight hours. The cases which the speaker had observed were all successful. The treatment of the duct appeared to secure validity of the sutures which so often part after insertion.

Michaux said that the procedure was common in his hands. Usually he first lifted up the duct to empty its septic contents into the bladder before removing the latter.

Routier added that cholecystotomy and washing is the best first step, because the bladder *in situ* is an excellent tractor for managing the duct during the exploration of it.

Schwartz claimed that more prolonged drainage than for forty-eight hours is necessary to provide against death by giving way of the sutures and consequent leakage.

Guinard in behalf of Pluyette (Marseilles) reported two cases of calculi of the urethra. The first patient, twenty years old, had developed a para-urethral stone in a diverticulum of the urethra during the past fourteen years. The second patient was forty-five years of age and suffered from an intra-urethral calculus which weighed sixteen grams and had reached considerable age.

Ricard at the meeting of October 10th described his method of cure of an obstinate case of vesicovaginal fistula, which had been subjected to several operations previously, the last being an occlusion of the vulva. This was followed by a highly annoying and painful cystitis, for the relief of which she came under his care. His first step was a wide denudation of the anterior face of the uterus, precisely as in the first stage of a vaginal hysterectomy. The uterus was then drawn far down and in this free space and with this thorough freshening of the edges the fistula was closed by suture and almost complete healing ensued. A minute fistula persisted which was easily closed at a second sitting.

Routier reviewed another case where there was too little tissue in the anterior vaginal wall for suture until the uterus was still further freed and drawn down. Cure in this case, previously considered beyond the reach of all surgery, was absolute.

Bazy condemned in unequivocal terms occlusion of the vulva and vagina in these cases.

Walther reported success by this method in an instance in which hypogastric laparotomy had failed.

Segoud recalled a patient upon whom he had done an exploratory subpubic cystotomy and discovered one of the urethral orifices in one of the margins of the vesical part of the fistula. In suturing this sinus he was most careful not to have the silk pierce the walls and form the nidus of a calculus and not to include the urethral mouth in the scar-line. A minute sinus persisted which was promptly closed after the manner described by Ricard.

Potherat contributed another case of urethral calculi. His was a phosphatic deposit about an oxalate of calcium center and found in a pocket of the canal. It was removed by external urethrotomy after having given symptoms simulating stricture for eight or ten years.

Chapot-Prevost (Rio de Janeiro) at the Académie de Médecine, October 2d, introduced one member of a xiphopagus monster subsequent to surgical separation. Both individuals were females. The other perished a few days after the interference apparently of a pleuropericarditis. In addition to the soft external parts and the bones which united the girls there was a large bridge of hepatic tissue and of pericardial sac, with a small canal connecting the two pericardial cavities. This seems to be the first case recorded where when the liver was involved the separation has not been fatal.

Vallin gave the report of Kitasato (Tokio, Japan) of two epidemics of the plague in the villages of Kobé and Osaka, comprising 69 sick and 63 deaths. The rats appear to have been the greatest single factor in the spread of the disease. The plague extended among the populace from November 18, 1899, to January 11, 1900. Up to the end of January 20,000 rats in Kobé and 15,000 rats in Osaka were found dead of the disease. The specific germ was found positively once in five examinations at Kobé and once in ten examinations at Osaka and very often many dead rats were found either in the same house or in the immediate neighborhood of the sick.

Salmon at the Société de Biologie, October 6th, rehearsed his results in his endeavor to prove the observations of Richet and Héricourt that raw meat is curative of tuberculosis among dogs. He divided his animals into three sets. To the first series he fed raw meat for a long time before the inoculation which proved fatal to all. To the second set the meat was given twenty days after the injections. Several gained in weight and survived a long time. The last series of dogs were allowed to become emaciated and cachectic before the raw meat-feeding was initiated. No effect whatever was observable among them. It is interesting to note that one animal suffering from tuberculous peritonitis was seemingly cured by the raw beef; but the autopsy revealed very numerous active young tubercles.

Bouchard said that thus far in the hands of numerous observers raw meat is of absolutely no value or of merely insignificant value, in tuberculosis among human beings. The successes reported for this method among dogs tend to show that their economy possesses a relation to raw meat which that of human beings does not.

Laveran has determined that the trypanosomes of the rat may be preserved alive for thirty to forty-five days by placing the blood containing them on ice. This fact is of value to those who have not previously found it possible to study them alive and their effects when they are injected into animals.

Fere reported the case of a man afflicted with a life-long general paralysis exhibiting a sexual excitement with the same periodicity after the first appearance of his disease.

Widal, at the meeting of October 13th, reviewed the observations of Sicard, Ravaut and himself upon the characters of the cephalorachidian fluid in tuberculous meningitis. As a rule no definite cells appear except when the meninges have been attacked by acute inflammation and then these vary in accordance with the nature of the excitant. In the tuberculous patients the fluid was at times turbid, or bloody, or so limpid as to simulate closely normal fluid. Microscopically, after centrifuging, there appeared a large number of lymphocytes, but exceptionally any polynuclear cells. On the other hand in cerebrospinal meningitis the latter cells were largely predominant. The conclusion is that possibly a diagnosis can be indicated by a microscopical examination of the fluid obtained by lumbar puncture.

Bacalogu presented a report of a series of experiments upon guinea-pigs with the bacillus typhosus. Living cultures were injected into the pericardium and after three or four days always they set up a pericarditis followed by myocar-

ditis and left-sided hemorrhagic or serous pleurisy. The same results were obtained by using inoculations of the bacilli killed by boiling. Other animals received doses of bouillon culture filtered through porcelain. No lesions were found in these. From these results he infers that the typhoid toxin resides in the bacillus and is not soluble in media as is the poison of the bacillus diphtheriæ.

Remlinger remarked upon the very pronounced rarity of all forms of tuberculosis in Tunis alike among the Europeans and the Jews, less so among the Arabs, so far as pulmonary forms go. He advanced the theory that the situation of the county, between the sea and the Sahara desert, involves a ventilation from north to south.

Bouchard attributed to unhygienic life and surroundings the greater frequency of tuberculosis of the lungs among the Arabs.

Nicolas (Lyons) submitted a note in which he stated that agglutination, at first absent, will appear among the bacilli of Loeffler after a long period of laboratory culture.

Pierre Merklen at the Société Médicale des Hopitaux, October 12th, submitted a minute of his observations of an epidemic of varicella in one family presenting peculiarities worthy of mention. The illness began with an eruption upon the trunk, so distinctly that just as soon as the vesicular lesions appeared on the face a fever was present, the vesicles of the chest and back were already drying up or actually casting off their scabs. Since the preliminary trunk eruption was almost entirely latent at its invasion and the contagiousness of the disease was precocious, the futility of any isolation precautions in the family would be at once apparent. In one of the four cases the vesicles remained citrine, there was no fever, the eruption was confined to the trunk and appeared only discretely upon the face and the extremities and desiccation and exfoliation occurred without scars. In the three other patients the vesicles of the face, hands and feet suppurated after three or four days of irregular and continued fever, dried very slowly and the crusts when cast off left behind distinct scars. One might distinguish, on the basis of these four cases, a variety of varicella with citrine vesicles, without fever and without scars and a variety with suppurating eruption, some fever and scars. Finally, it appeared that other preexisting skin lesions (eczema, excoriations of hands and feet and fleabites) contribute greatly to the abundance and character of the eruption. The causes of suppuration of the lesions are without doubt complex. All his patients were surrounded by the best conditions of hygiene, but an existing eczema certainly was a favoring factor of suppuration in the skin; so likewise the second who had an abrasion of the foot. The third, however, had an intact skin and the only reason why it became infected seems to be that a varicella once suppurating may transmit itself in that form, probably by mixed infection of the germs of varicella and of suppuration associated.

Sireday reported a case of typhoid fever in a man twenty-seven years old, the invasion and early course of which were usual until the twenty-first day when signs of involvement of the pleural cavity appeared. The needle withdrew a few drops of pus which contained numerous bacilli typhosi and a few rare pneumococci. A few days later several other punctures were made without definite result. The patient went on to complete recovery. This case deserves to be added to others of typhoid pleurisy, as described by Widal, who taught that the exudate is usually so scanty as not to warrant thoracentesis, although the physical signs may indicate quite a copious accumulation. This is due doubtless to the accompanying inflammation of the lungs which clouds the picture.

Gaillard presented the history of two typhoid cases with pulmonary infarct. The first patient was a twenty-four-year-old man who on the nineteenth day of his disease was overtaken by a sudden pain in his side, followed by a bloody expectoration but without temperature. A few days later there appeared at the base of the right lung signs of a slight pleuritic exudate, which soon absorbed, but left behind distinct adhesions. The second observation was upon a man twenty-one years old who on the twenty-first day had a similar attack with slight hemoptysis, dulness, subcrepitant râles and loss of respiratory murmur at the base of the left lung. These signs ameliorated and then pleurisy appeared with fever. Recovery followed. Exploratory puncture was negative in each of these cases, perhaps because the fluid was too thick or because it formed so thin a layer on the surface of the lung that the needle pierced the substance of that organ.

SPECIAL ARTICLE.

PLAGUE IN SAN FRANCISCO DURING OCTOBER, 1900.

San Francisco, Quarantine Station,
Angel Island, Cal., October 29, 1900.

Sir: In reply to Bureau letter of the 20th instant (C. H. W.), and in confirmation of telegram sent on the 27th, I have the honor to state that during the month of October 3 cases of plague have occurred in San Francisco among the Chinese. All cases terminated fatally. The first death occurred on October 5th, at 720½ Dupont Street. The patient was a cigar-maker, who had been working just previous to his last illness in a cigar factory on Battery Street. The history which was obtained from the acquaintances of the man was that he had been ill about four or five days before death. No clinical history of his illness could be obtained. The post-

mortem examination was limited to the removal of the enlarged femoral glands, which, on examination, both microscopically and bacteriologically, showed the plague bacillus. The bacteriologist of the city board of health submitted some of the gland tissues to me for an examination. This was examined in the laboratory at this station, with the result of confirming the diagnosis.

The second death occurred on October 10th at 767 Clay Street, in the same house whence a case of plague was removed to the city hospital, dying there on July 5th. This man had been ill for a week or more, and was treated by a white physician. The death certificate gave the cause of death "typhoid pneumonia." Dr. Kellogg informs me that on inspecting the body a mass of enlarged femoral glands was seen, which, on removal, showed evidences of acute infection. Microscopical and bacteriological examination demonstrated the cause of death to be plague.

On October 14th, at request of Dr. O'Brien, the Health Officer, I visited a case at 905 Clay Street, which was reported to present certain suspicious symptoms. This case gave a history of being ill for three and one-half days. The attack commenced with a rigor, followed by fever, giddiness, nausea, and vomiting. He was seen on the evening of the 13th by a white physician, who stated that his temperature was considerably over 100° F., pulse very rapid and weak. There was also nausea, vomiting, and slight diarrhea. On the following morning—the 14th—a considerable swelling of the glands in the femoral regions was observed. There was considerable elevation of temperature, and more prostration than existed the day previous. He then reported the matter to the health office as being probably a case of bubonic plague. The patient was seen about 5 o'clock on the same day by several physicians, *viz.*, Drs. Bulkley and O'Brien, of the health board; Dr. Bunnell, police surgeon; Dr. Ryfkogel, bacteriologist to the State board of health, Dr. Lumsden, myself, and Dr. Pillsbury. The patient presented the appearance of one profoundly ill with an acute infectious disease. His temperature was 103.5° F., pulse 140, soft and compressible. There was considerable delirium. Physical examination revealed an enlarged spleen and a mass of enlarged glands in the left femoral region. There were also several reddish spots over the chest and abdomen, having all the appearances of subcutaneous hemorrhages. Cover-slip preparations were made from the blood, and also of the fluid aspirated from the gland. Cultivations were also made from the gland and blood. Microscopic examination of the cover-slips demonstrated the presence of numerous diplobacilli, which morphologically resembled those of bubonic plague. These bacilli took on a bipolar stain with thionine, and were easily decolorized by Gram's method. The cover-slips made from the fluid removed from the gland contained countless numbers of these bacilli. In fact, it appeared more like that of a pure culture of plague than a specimen taken from the body. The patient died at 11 o'clock that night, and on the following day Dr. Kellogg, the bacteriologist, made a post-mortem examination, removing the spleen and mass of enlarged glands. These tissues on examination gave the typical appearances of plague infection.

On the following day, the 16th, colonies had developed in the tubes inoculated from the blood and gland. These were examined and found to be those of bubonic plague. Animal inoculations made from these cultures were in every way confirmatory.

The State board of health has limited its operations to simply observing what is being done in San Francisco. They have instructed their bacteriologist, Dr. Ryfkogel, to be present at all post-mortem examinations and make an independent investigation. All sanitary inspectors, who were for a time employed by the various members of the board of health at the instance of the Governor, have been discharged. Dr. Crowley, a member of the State board of health, stated to me on the 27th instant that the State board of health was of the opinion that for the time being the city board of health was able and ample to meet the requirements of the situation; that while there had been bacteriological evidence of the existence of bubonic plague, there were not sufficient clinical data to warrant any steps to be taken.

In conclusion, I would state that it is my belief that the area of infection is gradually growing wider, so that now there are only three blocks of the Chinese quarter proper in which there has not occurred, since March last, a case of plague. The conditions which will obtain in the next six months will be, in my opinion, conducive to a further outbreak. The Chinese population will, in a few weeks, be augmented by several thousand more than exists during the summer months. About 3000 Chinese return every fall from the salmon canneries of Alaska. Then at the end of the fruit-picking season, which now is rapidly drawing to a close, large numbers of Chinese who are thus engaged seek a temporary home in San Francisco during the winter months. These people to all intents and purposes are contract laborers, and are of the lowest coolie class. They live under the worst hygienic conditions imaginable. It would, therefore, not surprise me to see a number of cases of plague occurring among this class of people. I will transmit, as soon as obtainable, a map showing the infected area, as well as the number of cases which have already occurred. Respectfully,

J. J. Kinyoun,
Surgeon, U. S. M. H. S.

Public Health Reports.

Typhoid at Ithaca.—A number of cases of typhoid fever have developed in Ithaca the past week. A considerable proportion are students of Cornell University residing on the campus.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held November 1, 1900.

The President, William H. Thomson, M.D., in the Chair.

Cystitis and Bacteria.—Dr. William K. Otis read a paper on the etiology of cystitis. He said that it is now generally conceded that the cause of cystitis is some microbe. This was in fact one of the first diseases the microbic origin of which was demonstrated. Pasteur showed in 1858 that even in normal individuals the micrococcus ureæ might exist in the bladder and so alter the urine as to make it alkaline. He taught that this micro-organism might easily be introduced into the bladder from without and in 1864 suggested the sterilization of urethral instruments. In 1883 Guyon of Paris produced experimental cystitis by the injection of the micrococcus ureæ into the bladder. The microbe did not produce its pathological effect in the healthy bladder, but when congestion was brought on by tying the urethra of an animal cystitis always followed. At first this was thought to be the only microbe that caused cystitis, but soon many others were found to bear an etiological relation to the condition. Now it is known that there are some twenty microbes concerned in the causation of the disease. The most common of these is the bacterium coli commune.

Cystitis and Bacterium Coli.—The exact relation which this micro-organism bears to cystitis is as yet unknown. It is well known that it occurs normally in the human intestine. It exists under many different forms and has at various times borne a number of different names. In 50 cases of cystitis it occurred 47 times. In 25 cases of cystitis it was found 23 times. It is evidently the most important of the causative bacteria, yet it is well known that its presence alone is not sufficient to set up an inflammation of the bladder. A number of cases of bacteriuria have been reported in recent years in which, though the bacterium coli commune occurred in large numbers in cloudy, offensive urine, practically no inflammatory symptoms existed in the bladder.

Other Bacteria and Cystitis.—After the bacterium coli commune the most important microbes in cystitis are the three forms of staphylococci, especially the staphylococcus aureus, the streptococcus, a bacillus septicus that is found occasionally, the gonococcus, and the tubercle bacillus. The gonococcus does not as a rule prove to be a virulent micro-organism for the bladder. When symptoms of cystitis occur during an attack of gonorrhea it is because of secondary infection. The tubercle bacillus very seldom affects the bladder primarily.

Avenue of Infection.—The avenue by which infectious agents find their way into the bladder is not always easy to determine. The most frequent source is the urethra. They are either carried back on instruments, or they may occasionally find their way from the posterior urethra, or from a collection of pus behind a stricture. Oozing urine may prove a medium for the introduction of microbes into the bladder. When incontinence exists and the urine dribbles, drop by drop, the column of fluid is almost stationary in the urethra for some time. The bacterium coli may then find its way into the bladder, as it possesses good motility. The neighborhood of the anus and the ease with which these germs might be carried by the hand to the meatus makes this method of infection not unlikely.

Infection from the Blood.—An inflammatory process in any organ may give rise to metastases in the urinary tract. Usually the starting-point of such a metastatic condition is in the intestines. It has been proven experimentally that when a ligature is placed on the intestines of an animal, bacteria may get into the abdominal circulation and so find their way to the bladder. The bacterium coli commune is especially prone to do this. The infectious agent may come from an abscess in a neighboring organ, or may spread directly from the uterus or the rectum. It seems clear that bacteria occur not infrequently in the human circulation. They are eliminated by the kidneys and so find their way into the bladder, but usually without producing any inflammatory reaction. Some predisposition usually must exist before the bacteria can gain a foothold for their reproduction and development. The colon bacillus, especially, may find its way into the bladder without producing any cystitis. Guyon has had a patient who for thirty years has been passing the bacterium coli from his bladder, yet has not suffered from any vesical inflammation. Dr. Otis himself has had a case under observation for several years in which there is the offensive, stale odor so characteristic of the presence of the bacterium coli and in which these bacteria actually exist in very large numbers, yet there are no actual symptoms of cystitis.

Rovsing, an authority on cystitis, was so much struck by these facts that he considered the bacterium coli commune as a harmless inhabitant of the bladder, as it is in most cases of the intestines, and thinks that there is always some other micro-organism present which is the active agent in the production of the inflammatory symptoms. The luxuriant growth of the bacterium coli, he thinks, interferes with the demonstration of the presence of the other microbe. Tuberculous foci in either or both kidneys may exist for years and pour any number of tubercle bacilli into the bladder and yet no infection take place. The tuberculous process may spread from kidney to bladder by the ureter, or it may be the result of an abscess of the prostate rupturing into the bladder, or finding its way along the ducts to the urethra and thence into the bladder. The presence of a simple cystitis predisposes to

tuberculous cystitis. It is only when the vital resistance of the bladder is thus diminished that infection takes place. The presence of a foreign body, the congestion and trauma incident to retention of urine, may easily predispose to almost any form of bacterial cystitis. Guyon has shown experimentally that artificial retention is the surest method of arousing cystitis if pathogenic microbes are present. Hence there is the greatest necessity for scrupulous asepsis in the treatment of retention of urine by instruments or otherwise.

Gouty and Rheumatic Cystitis.—It was the custom to refer a good many cases of cystitis to the underlying constitutional condition that exists in gout or rheumatism. It is doubtful if they ever more than predispose the organ to infection. Cold was supposed to be another prominent factor in the etiology of cystitis. There are times when exposure to cold seems to be the reason for an exacerbation of an already existing cystitis, but it probably never causes an attack of the affection by itself. There are, of course, certain mechanical conditions, as the presence of a foreign body or certain irritants, as cantharides, turpentine and the like, which may cause vesical inflammation.

Prophylaxis.—The most important prophylactic measure is the thorough sterilization of instruments that are used in the urethra. Steel instruments, of course, can be readily and effectively cleaned by passing them through the flame of a Bunson burner. Soft rubber catheters can be absolutely sterilized by boiling. They should then be kept in a one-to-two-thousand solution of formalin or of sublimate until they are used. Silk and other catheters are not so easily cleansed. These should be washed well on the outside with warm soap-suds and on the inside by forcing a stream of suds through their caliber with a syringe. Guyon recommends dry heat and says that they can be effectually sterilized at 140° C. without producing any change in their texture. Boiling in plain water for five minutes has also been recommended. When this is done the catheters must each be wrapped separately in gauze, because if they lie in contact with one another adhesions take place during heating and the surfaces become roughened. Formalin vapor may also be used for the sterilization of these catheters and various apparatus are manufactured for this purpose. If formalin is employed the catheters should be washed out thoroughly after their exposure to the vapor, otherwise this substance will prove irritating to the urethra.

Directions to Patients.—When patients are to use the catheter themselves they should be given the most explicit directions as to the care that must be exercised in keeping the catheters aseptic. It is impossible to insist too much on this point, for, no matter how intelligent patients may be, the use of the catheter becomes in time a routine and serious neglect of precautions ensues. Even physicians become careless and do not take the necessary care in this matter. Martin's directions are the best. They may seem to the inexperienced needlessly detailed, but those who realize how serious vesical infection may prove will consider them justified by the conditions. The patient should have twice as many catheters as he needs to use in the twenty-four hours, and on alternate days his catheters should be thoroughly subjected to some assured method of sterilization. There is no use in attempting to limit the number of catheterizations. As a rule, the urine must be removed from the bladder often enough to prevent an uncomfortable collection of the fluid and also to avoid congestion. The presence of large amounts of urine so lowers the vital resistance of the bladder-walls that infection very easily takes place.

Lubricants.—A good lubricant is needed and should be in the form of some material that does not prove a ready culture medium for microorganisms. The lubricant substance should also be soluble in water, otherwise a collection of material may cling to the bladder-walls. There is at least one case on record where a large amount of vaseline was found in the bladder as the result of its frequent and abundant use for the lubrication of catheters. Sterile glycerine possesses many of the qualities of a good lubricant, but is too thin. Lubrichondrin has been recently introduced to the profession and is in many ways an ideal lubricant. It is sterile and is sold in tubes which assures its cleanliness much better than if it were in some ordinary receptacle. After the passage of a catheter the bladder should be washed out with a one-to-two-thousand formalin solution, or a dilute solution of nitrate of silver should be injected into the bladder and allowed to remain for three or four minutes. After this the bladder should be washed out. Various internal remedies which act as antiseptics in the urine are in general use and will often be found of assistance in the treatment of vesical conditions. Of these salol, methylene blue, and benzol are the best. Recently there has been introduced a new synthetic product, urotropin, which gives excellent satisfaction. In doses of seven and one-half grains given four times a day, this drug will often clear up cloudy urine that has resisted even the employment of vesical irrigation.

Predisposition Important.—In the discussion Dr. Edward L. Keyes said that bacteria are undoubtedly of importance in the production of cystitis, but some underlying condition of the system seems to be still more important in the etiology. He has frequently seen the condition known as bacteriuria, *i. e.*, hazy urine with a distinct mousy smell, accompanied by but very slight symptoms of vesical irritation. A few pus cells could be found in the urine, the haziness of it could not be thrown down by chemical reagents and the bacteria could be readily detected by culture methods. If the bacterium coli is pathogenic for cystitis it is evident that there

are conditions under which it fails completely of its effect. Not only this, but under certain circumstances, even when the bladder reacts distinctly to the irritant present, the general system does not seem to suffer and the individual remains in reasonably good health. Dr. Keyes has under observation at the present time a man whom he saw first twenty-five years ago. At that time the urine was putrid and the man was living an absolute catheter life. After a course of irrigation the condition improved; then the patient neglected himself and the conditions became worse than ever. A few years ago he saw the man again and found that he complained very little of vesical symptoms. He was still passing the catheter faithfully every day and the instrument was a sight. The catheter was all blistered and reminded one of nothing so much as of a rat-tail file. The patient employed no lubricant. The instrument was kept in a drawer in his office, or in a washstand at home, and no precautions as to cleanliness were taken. Not long ago the man was placed on urotropin and since then his urine has been perfectly clear.

Bacterial Infection.—Of late years it is becoming recognized that the mere presence of pathogenic microbes is not enough to produce disease. It is the old question of the seed and the soil. Only when the soil is capable of nourishing the plant will the seed grow. Long ago in the Good Book it was said that some seeds fell on good ground. Soil is more important than seed. When the tissues are rendered less resistant by sexual excesses, or by long sexual restraint, the incident congestion decreases the vital resistance and so makes favorable soil for the implantation of bacteria. At such times instrumentation or trauma may easily give rise to cystitis. The relation which predisposition bears to infection has been beautifully demonstrated by some experiments of Albarran. He injected into the circulation of an animal certain bacteria that had been isolated from a case of septic nephritis. These bacteria failed to produce anything but a local reaction, though some of them were found in the urine. When one of the kidneys of the animal, however, was deliberately bruised at the time of the injection, the bacteria found a lodgment in the kidney and produced a purulent condition. The uninjured kidney remained normal, though the bacteria in the circulation had also been carried to it.

Catheter Life.—At the beginning of catheter life patients are usually very sensitive to irritations of their urethra and bladder. Nature has not yet built up the protective mechanism which later so often effectually secures these patients against the effects of irritation and of infection. Even when all the details of asepsis are scrupulously put into practice, most patients will suffer from irritation and present hazy urine containing scattered leucocytes. Later many patients will be capable of standing almost anything in the way of urethral and bladder irritation.

Individual Vulnerability.—Dr. Bolton Bangs said that the occurrence of cystitis depends to a great extent on individual susceptibility. A patient of Dr. Bangs suffered so severely from cystitis that it was thought necessary to put in a retention catheter. The patient had to get up to the commode and the catheter slipped into the vessel. It was taken out by the patient himself and after simple wiping reinserted. An acute exacerbation of the cystitis resulted, but the symptoms subsided in a few days. It is not an unusual thing to find that old men who are living a catheter life carry the instrument in their hats. Yet such men often live to eighty and then do not die because of their bladder affection. The simpler the directions given to patients for the cleansing of catheters the better. Boiling constitutes the best and easiest means of sterilization. The importance of a good sterile lubricant cannot be overestimated. Dr. Bangs considers lubrichondrin the best now to be had. It is extremely important to maintain the general health of patients who are living a catheter life.

Catheter Hats.—Dr. Keyes said that it is a well-known fact that one of the prominent hatters on Broadway years ago made a special hat for old men in the bottom of which was a compartment in which a catheter could be placed.

Failure of Tolerance.—Dr. Eugene Fuller said that the cases which grow so very tolerant to catheterization are the exception and not the rule. They come as such a surprise that they were apt to be remembered. Dr. Fuller considers that cystitis is very frequently the result of a mixed infection. The gonococcus alone, for instance, very seldom produces cystitis. When some other bacterium, also pathogenic in its effect, is present in the bladder at the same time, the two may cause serious inflammatory symptoms.

Cleanliness.—Dr. A. B. Johnson insisted that certain simple precautions as to cleanliness often prove of great service in preventing the occurrence of cystitis. Patients should not only be instructed to boil the instruments they use, but should be made to wash the hands carefully and to wash off the glans penis and the meatus very thoroughly before the insertion of the instrument. In addition to these instructions they should be provided with tubes of lubrichondrin. The most important thing after instrumentation is to wash out the bladder. Utzmann of Vienna took very few precautions with his instruments, in fact always used the same sound even for successive patients without sterilization and yet never produced cystitis. He was very careful, however, to wash out the bladder thoroughly after the use of the instrument.

Irrigation of Urethra.—Dr. Valentine said that the urethra is constantly full of pathogenic germs. The danger of carrying these back into the bladder can be minimized by irrigation of the anterior urethra before the passage of the catheter into the bladder. If the irrigation is done with boric-acid solution and the urethra then

filled with an iodoform-glycerine solution, there is very little danger of setting up inflammatory reaction either in the urethra or in the bladder. The importance of clean catheters is emphasized by the recent reports of five cases of vesical calculus, the nucleus of the stone in each case being a hair that was carried in on a catheter.

Vulnerability.—Dr. Jacobi said that the question of infection depends to a great extent on the vulnerability. This may vary from time to time even in the same individual. There are times when the bacterium coli becomes pathogenic even in the intestines. Normally, however, it exists there in millions without doing any harm. Why then should it not occasionally exist in the healthy bladder without producing cystitis? This would not preclude the possibility of its producing cystitis under more favorable conditions. The opportunity for this micro-organism to find its way into the bladder by direct contact is comparatively easy in the female, from the anus into the vagina. There is no doubt that at times broncho-pneumonia is caused by the bacterium coli which finds its way into the mouth and respiratory passages from soiled fingers. Ordinarily its presence does not produce any pathological conditions, but if catarrh of the respiratory passages already exists it may easily cause further pathological developments in the respiratory tracts. The same thing is true in the gall-bladder into which bacterium coli finds its way, but proves pathogenic only when the resistive vitality of the gall-bladder is lowered or the virulence of the micro-organism itself has been increased by some enteritic condition.

In closing the discussion Dr. Otis said that at the initiation of catheter life very great precautions should be insisted on. For several days beforehand urotropin should be administered in order to make the urine aseptic and unirritating. Just before catheter life is begun the patient should even be counseled to pass a day or two in bed until he becomes accustomed to the new conditions. Gentleness in the passage of instruments and cleanliness remain the most necessary imperative precautions.

BOOK REVIEW.

An Inquiry into the Conditions relating to the Water Supply of the City of New York. By the Merchants' Association of New York. August, 1900.

It is a pleasure in this day and generation, when universal egoism threatens to stamp out ethical standards and altruistic endeavors, to find a group of citizens, who at great personal expenditure of time, energy and money, are willing to give their best efforts to the public welfare in the battle with political greed and robbery.

The present volume of 627 pages presents a complete review of the water problems of a great city and also exposes the many ramifications of the Ramapo Water Scheme.

The technical economic and engineering features of the problems involved are adequately discussed and the book is well worthy of a wide reading by financier, engineer and tax-payer. To the Merchants' Association should be accorded the thanks of the citizen and the support of the profession.

BOOKS RECEIVED.

Heart Disease in Childhood and Youth. By Dr. C. W. Chapman. Demi 8vo., 101 pages. Illustrated. The Medical Publishing Company, Limited, London. Ninety cents.

A Practical Treatise on Genito-Urinary and Venereal Diseases and Syphilis By Dr. Robert W. Taylor. Second Edition. 8vo., 722 pages. Illustrated. Lea Brothers & Co., New York and Philadelphia.

Hernia, Its Etiology, Symptoms and Treatment. By Dr. W. McAdam Eccles. 8vo., 231 pages. Illustrated. William Wood & Company, New York.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. Edited by Dr. Thomas L. Stedman. Vol. 20. Tuberculosis, Yellow Fever and Miscellaneous. 8vo., 906 pages. Illustrated. William Wood & Company, New York.

ORIGINAL ARTICLES.

ŒDEMA BULLOSUM VESICÆ.

BY FREDERIC BIERHOFF, M.D.,
OF NEW YORK.

Of the forms of edema which affect the human bladder that which Kolischer ("Erkrankungen der weiblichen Harnröhre und Blase") describes as "edema bullosum" is perhaps the most characteristic, and certainly the most interesting.

To quote his description of this condition, which is classic in its exactness: "Circumscribed portions of the vesical mucous membrane appear to be covered with clear vesicles varying in size from a small seed to a pea; between these frequently closely-crowded vesicles one sees white particles floating, which are adherent at one extremity to the bladder-wall and are, in all probability, the remains of the membrane of vesicles which have already ruptured. In especially exquisite cases, this formation of vesicles is, with regard to their size and number, an exceedingly large one, so that one inclines to the belief that one sees a part of a hydatid mole." He also states that in each case in which he saw this form of edema, it occurred at a part of the bladder-wall to which an adjacent inflammatory tumor had become attached or when a pus-tumor had broken through into the bladder, leaving a fistulous communication, however, so that the purulent contents of the tumor remained under pressure. The finest forms, he states, occur where an exudate exists between the uterus and bladder, and adds that he does not hesitate to designate the occurrence of this phenomenon as an indication of the inflammatory nature of a tumor adjoining the bladder.

With this statement my experiences with this condition lead me to agree fully, as also with the further one, that he has only seen it occur in cases of carcinoma uteri when inflammatory changes in an ulcerating carcinoma of the cervix have led to infiltrations in the region where the cervix and bladder are connected. But that, in such cases, the bullæ occur only as isolated formations, I cannot accept as true for all cases, for in some of the cases of carcinoma which I have examined the picture was exquisite with regard to the extent and characteristic development of the condition. In fact, in the later stages of carcinoma of the uterus and parametrium, where the process had extended to and involved the bladder-wall, the picture was clearer and the process more extensive than with any of the other causes.

Since the condition is due to the lifting up of the superficial epithelium of the bladder by exuded serum, it may be caused by any condition, inflammatory or neoplastic, which obstructs the circulation in any part of the bladder-wall. Hence, the nearer these causative processes approach the mucous surface of the bladder, the more pronounced will be the edematous condition. Casper ("Handbuch der Cystoskopie") mentions having seen edema bullosum in a number of females; and also in males, especially where tumors of the prostate were present, which protruded high up into the bladder. In such cases he says, it is found on the floor of the bladder. In one case of prevesical abscess in the male he also found it on the upper wall. He also claims to have seen this phenomenon in the neighborhood of vesical tumors, surrounding these with a wreath of vesicles. He concludes that its seat is at that part of the bladder-wall where the interference with the circulation is the most marked, and that it is never to be found in a bladder which is entirely normal. But he also remarks upon the difficulty which at times arises in the attempt to differentiate between edema bullosum and fimbriated tumor-formations.

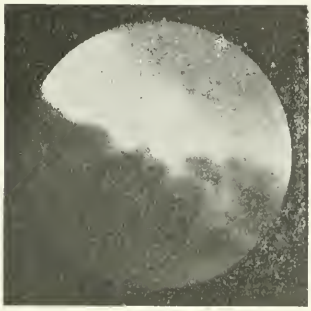
One of these conditions, a hypertrophic form of cystitis, described by me (MEDICAL NEWS, May 26, 1900) under the designation "cystitis papillomatosa," or villosa, at times closely resembles edema bullosum. In differentiating between the two, or between edema bullosum and the minute papillomata which occur at, or near the inner sphincteral margin, we must bear in mind that while in edema bullosum we have to deal with vesicles filled with clear, transparent serum, in cystitis papillomatosa we find an inflamed surface covered with minute papillæ, which, on closer examination, are found each to possess a vascular loop. Similarly, also, with the minute, discrete papillomata at the sphincter. These last-mentioned are found at times on or just behind the margins of the sphincter, and are, when small, perfectly transparent, excepting for a beautifully clearly-defined vascular loop. When larger they lose partially or completely their transparency, but the vascular loop may almost always be distinguished, if not throughout the entire growth, then near the free end at least, where the main growth at times becomes somewhat fimbriated.

They may give rise to dysuria of a varying degree of severity, and may occur as an accompaniment of mild, catarrhal inflammations about, or at the sphincter, or without any discoverable inflammatory accompaniment. Lastly, whereas the bullæ of the edematous process tend to assume a hemispherical or lenticular form, the pa-

pillomatous processes take the form of slender, long tongues, with rounded, or even clubbed ends.

In all, fifteen cases of typical edema bullosum have come under my observation. They were as follows: Carcinoma (affecting uterus and parametrium), 4; catarrhal cystitis colli, 4; suppurative cystitis colli, 1; gonorrheal cystitis colli, 1; ulcerations, superficial, following cauterization with cystoscope, 2; pyosalpinx with parametritic exudate, 1; cystocele (without discoverable inflammatory changes in the vesical wall), 1; urethritis (involving, also, the vesical sphincter-margin), 1.

Fig. 1.



Papillomatous growth at and near sphincter vesicæ, in a case of cystitis gonorrhoica.

Where it occurred as an accompaniment of carcinoma, the latter had, in every case, spread from the uterus to the parametrium and thence to the bladder-wall. In all four the base of the bladder, either at, or just above the ligamentum interureterieum, was affected, and was marked by pronounced transverse folds involving, in three cases, either one or both ureteral orifices, in the fourth leaving both unaffected. The diseased parts of the bladder-wall were, in each case, covered with edematous, or congested and edematous mucous membrane, marked with numerous, transparent bullæ. The vesical symptoms complained of were, in two cases, frequent and painful urination, and, in the other two, diurnal and nocturnal incontinence of urine. In the first two cases, the character of the urine indicated inflammatory vesical changes, in the last two it was entirely normal, giving no microscopical evidences of inflammatory reaction.

In the four cases of catarrhal cystitis colli, as also in those of suppurative and gonorrheal character and in that of urethritis, the circumference of the sphincteral margin was marked by discrete, transparent vesicles. In one case the trigone also was affected; the rest of the bladder was normal.

The symptoms, in each of these patients, were those of the original condition, *viz.*, cystitis or urethritis, abnormally frequent urination, with a varying degree of pain, or tenesmus. In those cases where it was an accompaniment of an ulceration due to cauterization with the cystoscope-lamp, it was not seen until the reaction had been in progress for several days, and the burnt surface had begun to slough away. In both cases the bullæ formed immediately at the circumference of the ulcer. In neither case was there any symptom referable to the ulcer, although one occurred in a case of suppurative cystitis. Where it occurred in the course of a pyosalpinx and accompanying parametritis, the bladder-wall covering the tumor was found to bulge decidedly inward, to be edematous, and the seat of several ecchymoses and a number of transparent pea-like vesicles.

Here, again, the vesicles were, due to their transparent nature, recognizable chiefly by the shadows which they cast. Appropriate treatment of the exudate, which was followed by diminution in the size of the tumor, as well as regression of the inflammatory symptoms, was also followed by complete disappearance of the edema bullosum. Where it accompanied a cystocele, in an elderly female, the region of the lower margin of the sphincter, and the trigone were the seat of the vesicles. No signs of inflammatory changes were discoverable in this case, nor were any other physical symptoms than nocturnal and at times diurnal incontinence of urine present. Suspicion of carcinoma was not verified, although repeated, careful gynecological examinations were made with the view to determine this point.

I am not inclined to ascribe decided diagnostic value to this phenomenon, as it seems to occur as an accompaniment of many different inflammatory or infiltrative processes. I agree, however, with the views of Kolischer and Casper, that its presence denotes the extension of an inflammatory or infiltrative process to the bladder-wall, and its approach toward the mucous surface.

THE OPERATIVE TREATMENT OF UGLY EARS.[1]

By JOHN B. ROBERTS, M.D.,
OF PHILADELPHIA;
PROFESSOR OF SURGERY IN THE PHILADELPHIA POLYCLINIC

EVEN within what may be termed physiological limits great variation exists in the size and contour of the external ear. Disfigurement occurs, however, when there is a disparity in the size of the two organs, when any other condition of asymmetry is present, or when a marked variation from the usual size, position or contour exists in one or both auricles.

This short paper is presented to the Society to direct the attention of its members to the great improvement possible in many auricular deformities. A recent French author has intimated that all medical men should be cognizant of the possibilities of modern aseptic surgery; because, even if unprepared or unwilling to undertake certain operative procedures himself, every practitioner should be at least familiar with the fact that in given conditions operative relief is possible and perhaps imperative. This same line of argument holds good in the case of unsig conditions of the ears. Many persons care little for personal appearance and are not affected by the existence of a deformity which would make another individual morbidly sensitive and very unhappy. It seems well, therefore, for all surgeons to study with some degree of earnestness the correction of auricular defects. The subject is perhaps the more worthy of attention as operative treatment for the correction of these conditions is free from risk and usually unaccompanied by confinement to bed or even absence from business pursuits.

A lacerated or incised ear should be subjected to thorough sterilization and careful suturing, so that the irregular surface may match that of its fellow. Fine silk is probably the best suture material. Wisdom in directing the course of the needle through the tissues will enable the surgeon to preserve the shape of the organ and make a very good ear even after considerable loss of structure.

After the removal of tumors or the occurrence of sloughing from burns, frostbite or injury, much artistic skill is occasionally demanded order to restore the symmetry of the two ears. It may at times be necessary to alter the shape or size of the uninjured ear, to obtain a proper correspondence with the one which has been subjected to a traumatic change. If material is needed to take the place of lost tissue, it is to be transferred from the neck or cheek or transplanted from the hand, abdominal wall or thigh. A portion of a finger or a flap from the palm of the hand may be utilized; or a thick flap from the front of the abdomen or the thigh may be first grafted upon the hand and two or three weeks later fixed to the stump of the ear. Such a mass of muscle, fascia and skin is then modeled into proper shape by a series of minor operations.

[1] Read by title before the Medical Society of the State of Pennsylvania, Wilkes-Barre, September 20, 1900.

The deformity due to tearing out earrings or to the simple piercing of the lobule for these ornaments requires excision of the cicatrized margins of the fissure or orifice and neat suturing. The proceeding is practically the same as that to be adopted if a native of Africa or the South Seas desired relief from the disfigurement left after discarding the customary nose-ring or lip-plate.

Some deformities or distortions may be corrected by orthopedic means, such as pads or springs, or by repeated applications of collodion Artificial ears have been constructed of metal and other materials, and it has been suggested to imbed plates of platinum within the tissues to give rigidity to flaccid parts.

Congenital nodules in the region of the ear, sometimes called supernumerary auricles, are to be excised; unless they can be used to advantage in correcting the shape of the true auricle, in case it be misshapen. Fistulæ in the same region are to be closed by dissecting out the tubular tract and neatly closing the resultant wound.

Very large ears may be successfully reduced by excising a wedge-shaped piece, or by removing a crescentic piece from the central portion of the auricle and a horizontal strip outward from the centre of the convex margin of the crescent. It is not rare for the auricles to seem exceedingly large, when the real cause of the uncomeliness is the manner in which they stand out from the side of the head. Flaring ears seem elephantine when not much above normal size. The two conditions may coexist. The deformity then becomes very conspicuous.

Flaring ears are corrected by excising a vertical ellipse of skin and fascia from the posterior surface of the auricle and the adjacent po of the skull, and then cutting a vertical wedgelike strip from the exposed cartilaginous structure of the organ. Sutures are then employed to sew the auricle close to the skull. Bandages or spring pads are to be used until the union is sufficiently firm to prevent tearing of the scar tissue by unexpected movements during sleep. If a condition of gigantism coexists with the flaring, the operation for reduction of the size of the auricle may be done at the same time. A similar method is to be employed in lap ears, in which the auricle droops forward because of imperfect development of cartilage. The displaced organ should be sewed to the scalp in such a way as to neutralize the tendency to droop. It might be possible to stiffen the auricle by inserting a thin sheet of metal in the tissues. Perhaps such an implanted metallic strip could be bent, after it had become encysted, to resemble more closely the ridges and hollows.

Absent ears, from a want of development during intra-uterine life or from accident, may be represented by celluloid, papier maché or platinum constructions, properly tinted. Instead of these appliances, repeated plastic operations may be successful in making a rude representation of the normal ear.

THE HYDRIATRIC TREATMENT OF TUBERCULOSIS.[1]

By J. H. KELLOGG, M.D.,
OF BATTLE CREEK, MICH.

(Concluded from page 768.)

Reports of a few cases are appended which are presented as illustrations of what may be expected of rational hydriatric treatment conducted under favorable conditions. An elevated region is unquestionably necessary to secure the best results from hydriatric treatment, nevertheless the experience of Winternitz, Aberg, as well as my own, has clearly demonstrated that it is possible to effect a cure of tuberculous disease of the lung by hydriatric treatment without this advantage.

SQUARE CHEST PACK. (1.)
Fig. 13.

Case I.—Rev. G. T. came under my care in the autumn of 1866. I found a cavity as large as a hen's egg in the left apex. The patient was expectorating freely; portions of the yellow elastic tissue and great quantities of pus were constantly present in the sputa. He had an even temperature of 103° F., pulse was 90 to 100, breath exceedingly short. The patient was greatly emaciated and scarcely able to walk. I pronounced the case a hopeless one and advised the patient to return home, but he refused to do so and insisted upon receiving treatment. He showed so much pluck and determination that I thought I ought to give him a chance. The result was that in four months the patient returned home with a normal temperature, only a slight cough, very little expectoration, and pulse 60. He was able to walk several miles and to resume his profession as a clergyman. After a few months more spent under my care by my advice he went to Colorado to reside. For many years I heard from him frequently and he always represented himself as enjoying good health.

After seeing so many cases of recovery from this dread malady by the employment at the Battle Creek Sanitarium of the measures named, I determined several years ago to secure if possible the same advantages for patients in a dry and elevated region. Within the last five years the establishment of a well-equipped sanitarium under the same auspices at Boulder, Colo., has afforded opportunity for observing the progress of patients under rational treatment at an elevation of between five and six thousand feet. The large number of recoveries which have occurred, and the astonishing rapidity with which they have taken place in many cases have convinced me that by a combination of thoroughly rational and physiological treatment with climatic advantages, a cure may be secured in seventy-five or eighty per cent. of all cases of consumption when treatment can be begun in the early stages of the disease and in perhaps forty or fifty per cent. recovery may be expected in cases in which the disease has attained to the second stage before treatment is begun. Recovery may be expected in a small proportion of cases even when the disease has made still greater advances.

The following report of cases of pulmonary tuberculosis successfully treated by hydriatric measures at the Boulder Sanitarium, Boulder, Colo., has been kindly furnished by Dr. W. H. Riley, Superintendent of the Boulder, Colo., Sanitarium.

Case II.—Mr. B., from Ohio, aged twenty-eight years. Gave history of tuberculous trouble in his family. The patient had enjoyed fairly good health up to about three years previous to placing himself under my care at the Colorado Sanitarium. At about this time, that is, three years previous to his coming under my care, he had bronchial trouble from which he partially recovered. Later his cough increased and he began to expectorate and had a temperature of 101.5° to 102° F. at night. When he came to the Colorado Sanitarium he had a bad cough, expectorated and had a temperature of 101° F. at night; was very weak, thin, and anemic, and could walk only a few rods at a time. The physical examination of chest revealed a partial consolidation in the upper and middle lobe of the right lung, and the bacilli of tuberculosis were found in the sputum. He was placed under treatment and soon began to improve. His cough and expectoration disappeared and his temperature receded to normal. The improvement continued, and at the end of six months he had gained twenty-two pounds, weighing more than he had before in his life. Cough and expectoration had entirely disappeared. He had no rise of temperature and no

[1] Read before the American Climatological Association, Washington, D. C.

signs of lung trouble. I examined this patient about a year after he was dismissed from treatment and at this time there were no physical signs of any disease in his lungs. I have had

SQUARE CHEST PACK. (2.)

Fig. 14.

opportunity to see this patient at frequent intervals for nearly four years. He has had no rise of temperature, no cough or expectoration, and no physical signs of the disease up to the present writing. He is at present a prominent lawyer in the city of Denver, and enjoying a successful professional career.

Case III.—Mrs. B. F. J., from Alabama, gives following history: Grandfather, grandmother, brother and husband died of tuberculosis of the lungs, the last six months before the patient came to Colorado, August 2, 1899. Patient has never been strong, but felt well until twelve years ago, when she had an attack of typhoid fever. Has not been as well since. During the past three years has had more or less trouble with the stomach and bowels, indigestion, etc. In the fall of 1898 her physician discovered that she had tuberculosis of the lungs. Has had some cough, some expectoration, and some slight rise of temperature in the afternoon for some months previous to coming to the Colorado Sanitarium. When the patient entered the Sanitarium she was very thin, pale, anemic, and had distressing symptoms of indigestion in her stomach and bowels; had great difficulty in finding anything she could eat, and her food always gave her more or less distress; poor circulation, cold extremities, some cough, some expectoration, temperature 99 to 99.8° F. in afternoon. Physical examination of the chest showed partial consolidation of the apex of the right lung. The bacillus of tuberculosis was found in the sputum. Patient was placed under treatment, and for the first few weeks did not seem to make very much improvement. Stomach and bowels continued to give her very great trouble. By careful regulation of the diet and other treatment this difficulty was overcome. Patient remained under treatment at the Sanitarium for about four months. After the first few weeks of her sojourn she began to improve, and from this time on until she left the Sanitarium her improvement was gradual and quite rapid. When she stopped treatment November 28th, she had no cough, no expectoration, no rise of temperature. Physical examination of the chest showed that the lung was almost entirely clear. She had gained twenty-eight pounds in flesh. She remained in the city after leaving the Sanitarium and was under my professional care. At the end of another two months patient had gained forty-four pounds in flesh, had rosy cheeks, hard, strong muscles, and no signs whatever of any disease of the lungs, stomach or bowels. At the time of present writing patient is still enjoying good health and still holding to the flesh she gained. She weighs more than ever before in her life and is strong and healthy in every respect.

Case IV.—Mr. H., from Pennsylvania, aged twenty-four years, came to the Sanitarium October 18, 1899. Patient gives no history of any hereditary trouble in family. One brother died

SQUARE CHEST PACK COMPLETED. (Front View.)

Fig. 15.

of diabetes. Two years previous to his coming to the Sanitarium he spit up blood, a mouthful at a time, and at different time had slight hemorrhage. Some four or five weeks before coming to the Sanitarium his physician made an

examination of the sputum and found the bacillus of tuberculosis present. When patient entered the Sanitarium he had cough, expectorated considerably, pain in his chest, an evening rise of temperature, night-sweats, loss of flesh, troubled with shortness of breath, cold extremities, and weak action of the heart. Was thin and unable to walk more than a short distance without fatigue. On physical examination of chest there was found dulness on percussion, and diminished respiratory murmur in upper part of right lung, and the same signs but to less degree in the upper part of left lung. Patient also had more or less trouble with stomach and bowels with symptoms of indigestion. Patient remained from October 18th to February 21st.

SQUARE CHEST PACK COMPLETED. (Rear View.)

Fig. 16.

When he left the institution, had gained eighteen pounds in flesh, had no expectoration, the cough was practically all gone, and the temperature was normal. Physical examination of the chest showed some slight physical signs of thickening of lung tissue in the upper part of right lung.

Case V.—Miss E., aged twenty-two years. Family history negative. Came to the Sanitarium October, 1898. Four years previous to her entering the Colorado Sanitarium patient had slight hemorrhages at different times for about one week. Blood came up while coughing. She thought she completely recovered from this and enjoyed very good health for a time. About one year before coming to the Sanitarium she coughed up little blood again. In July, 1898, she had quite severe hemorrhage from lungs, and has not been well since. Three years ago she took a bad cold and has had severe cough since. When the patient entered the Sanitarium she had cough, expectoration, flushed face, and was pale about nose and eyes. Pulse sitting was 92. Temperature at noon and in the afternoon 99.4° to 99.8° F. Patient was weak, not being able to walk far without becoming tired. Had lost considerable flesh. She also had more or less trouble with stomach and bowels, with poor circulation. Physical examination of chest showed dulness on percussion in apex of right lung. Diminished vesicular murmur, and subcrepitant râles over the same area. She also had some trouble with her throat which was tuberculous in character. She remained under treatment until March 11, 1899. When she stopped treatment she had gained very much in flesh and strength, had scarcely any cough, no expectoration, no rise of temperature, and was feeling well and strong.

Case VI.—Mr. F. R. Park, from Georgia. Aged twenty-three years. Came to the Sanitarium December 17, 1897. Family history, negative. Patient's health began to fail years previous, during which time he suffered from indigestion while at school. Had severe cough which lasted four or five months. When he came to the Sanitarium had cough, expectoration, temperature of 99° to 99.5° F. in the afternoon. Symptoms of indigestion with poor circulation. Patient was very thin, anemic and week. Physical examination of chest showed marked dulness on percussion and bronchial breathing over apex of the right lung. Was placed under treatment and soon began to improve. Continued treatment until May 10th, at which time he had gained fourteen pounds in weight, and had no cough, or expectoration, and physical examination of chest showed that the partial consolidation of right lung which was present at the beginning of treatment had almost entirely disappeared. I have watched this case now for nearly three years. The patient is an active business man in Colorado and is enjoying the best of health at the present time, which is nearly three years since he was treated for tuberculosis of the lungs.

Case VII.—Mr. M., aged twenty years, from Wisconsin, came to the Colorado Sanitarium in July, 1896. Patient's mother had some lung trouble the nature of which is not known. The young man had usually enjoyed good health previous to the beginning of his lung trouble, which was in the spring of 1896. His trouble began with night-sweats, cough, expectoration, and he also lost considerable flesh. A few months after the appearance of these symptoms patient came to the Colorado Sanitarium and placed himself under treatment. When he came he was pale, anemic, and weak, with an evening rise of temperature. Physical examination of chest showed considerable thickening and consolidation of tissue in upper part of left lung.

Examination of sputum showed presence of bacillus tuberculosis. As soon as placed under treatment he began to recover and made rapid improvement. Temperature was soon reduced to normal. Cough, expectoration, and night-sweats disappeared. In a few weeks he had gained forty-five pounds in weight and proportionately in strength. During part of the time he gained one pound per day. He looked well, ruddy appearance, large physique, well filled out, and gave every indication of robust health. Something like a year after the patient was dismissed from the Sanitarium I had an opportunity to examine his chest again. There were no signs, whatever, of the disease. I have had an opportunity to watch this case now for nearly four years. The young man has been engaged in heavy manual work the greater part of the time and is enjoying the best of health.

Case VIII.—Mrs. B., from Kansas, came to the Colorado Sanitarium October 10, 1899. Patient gave history of consumption on father's side of family, also had one sister who died of pulmonary tuberculosis. Patient had the grip in 1898 which left her with cough. She had coughed and expectorated since, and her general symptoms grew worse. When she came to the Sanitarium her symptoms were as follows: Appearance very poor, tongue heavily coated, white and dry. Digestion very much impaired, much constipated, high raging fever in the afternoon and temperature of 103° F. or above. Pulse 120 or more sitting. Patient very thin and very weak, respiration very rapid, dyspnea, and at times her general condition indicated approaching collapse. She was very anemic, and very weak. Could walk but a few steps at a time. Physical examination of chest gave evidence of large cavity in lower part of left lung and physical signs of consolidation throughout the remaining part of left lung. Also crepitant and subcrepitant râles over greater part of left lung. Also some physical signs of consolidation in upper part of right lung. This patient was placed on rest cure, and given such food as could be easily digested. Was given cool wet hand-rubs, cool mitten-friction in the evening with cool compress on chest, changed every fifteen minutes, and kept up from one hour to one hour and a half, and followed by cold moist pack on chest which was worn through the night. This treatment was given every afternoon and evening while the temperature was highest. In the morning while temperature was lower, the patient was given hot and cold to the spine, with dry friction and oil-rub. Patient also used nebulizer containing creosote and other antiseptics. Bowels were kept open, and patient was requested to drink freely of water. The results of this treatment were most gratifying in this case of advanced pulmonary tuberculosis. It should be observed that the temperature of this case was 103° F. or more in the afternoon and had been so for some time before the patient came to the institution. After one day's treatment the temperature dropped from 103° to 101.3° F. The next day or two there was a fraction of a degree rise, but this again receded and gradually declined. After one week's treatment the highest temperature was 100° F. in the afternoon. The patient only remained under treatment about two weeks, but the improvement was very marked in every way when she left the Sanitarium, her temperature was about 100° F. in the afternoon. The appetite was much improved, breathing very much slower and deeper. General condition much improved and with her friends she took an overland trip in an open wagon to her friends in Kansas. This patient might have been improved more had she remained under treatment longer. She discontinued treatment contrary to advice. This last case represents a class of cases that come to the institution in the advanced stage of the disease. These cases as a rule are not cured, but many are benefited, and the results of treatment as illustrated in this last case show clearly the beneficial effect of hydriatric treatment when properly selected and rightly applied, even in the advance stages of pulmonary tuberculosis.

Summary.—The essential features of rational hydrotherapy as applied to pulmonary tuberculosis may be summarized as follows:

1. Both general and local cold applications to the skin.

2. Careful graduation of the application both as regards its intensity, duration and frequency, by modifying the temperature and mode of procedure, keeping always within the limits of the patient's ability to react. The best methods for accomplishing this are dry friction, wet hand-rubbing, wet mitten-friction, cold towel-rubbing, wet sheet-rubbing, half-baths, the general douche.

3. The application of compresses, hot and cold, as a means of relieving pain and controlling the local blood-supply, especially the use of the chest-pack to relieve cough and to aid the tissues in combating the disease and the employment of the hot sponge-bath and various other hydriatric means for relieving special symptoms.

I regard a dry elevated region a condition essential for the best results in the majority of cases. In observations upon some hundreds of cases during the last twenty-five years, I have seen excellent results at altitudes ranging from 1500 to 5500 feet. The constant applying of stimuli of various sorts upon the skin, such as sunlight, variations of temperature, etc., are an important means of maintaining vascular tone in the internal parts of the body and in stimulating metabolism and general functional activity. By hydrotherapy we are able to exaggerate or diminish the impressions sent inward from the skin and thus to control nearly all the bodily functions to a marvelous degree.

In fairness I must say that I have seen good results in cases in which hydriatric treatment has not been systematically carried out. I must also record the fact that results have unmistakably

been far more uniform, more permanent, when hydriatric treatment has been employed in connection with climatic change. For a number of years back I have been in the habit of sending cases of this class to the Colorado Sanitarium at Boulder, Colo., or the Guadalajara Sanitarium at Guadalajara, Mexico, where patients have the advantage of thorough hydriatric treatment and the results have certainly been excellent. Not all patients have recovered, by any means, and it is very difficult to say in any case that an absolute cure has been effected.

In advanced cases in which the breaking down of lung tissue has advanced to the formation of large cavities and when large areas are involved the prospects for a radical cure by hydriatric methods is of course small, nevertheless in even these unpromising cases a marvelous degree of improvement is often secured and the patient's life prolonged for many months and even years.

ABSORPTION, MOTILITY AND DIGESTIVE POWER OF THE STOMACH.[1]

By A. E. AUSTIN, A.M., M.D,
OF BOSTON.

IT is evident that undue importance is being attached the the secretory power of the stomach. To the determinations of HCl great interest has been given, perhaps on account of the fact that this was one of the first and most tangible substances in stomach-contents which could be determined, and pages have been written on anacidity and hyperacidity of the stomach. While allowing to this a moderate share of the importance which has been given it, we must bear in mind that secretion is not by any means the only function of the stomach. It is a well-known fact that in anacidity there always exists a compensation between the amount of HCl lacking and volatile acids, chiefly lactic, acetic, etc., which, with the aid of pepsin, can to a large extent digest the food which enters the stomach.

The discomfort arising from this condition appears to be due not to failure of digestion, but to the gases which are formed coincidently with the volatile acids. Boas has called attention to the presence of sulfureted hydrogen, while others have also called attention to hydrogen, CO_2, etc. Von Noorden, who has performed a number of experiments in this connection, in his "Pathologie des Stoffwechsels" (pp. 241-247), expresses the following view: "If HCl is wanting in the gastric juice, its loss is not seriously felt, because, if the contents are promptly poured into the duodenum, their further digestion is completed by the pancreatic juice, and examination of the fæces shows no greater loss of nitrogenous material than as though the HCl were present in normal amounts. Hyperacidity, or, rather, hyperchlorhydria, has rather more serious results on account of the attacks of pain which are produced by this highly acrid secretion. The digestion, however, is no more seriously affected than under the former conditions, because this highly acid solution, promptly neutralized by the alkaline secretions of the intestines, undergoes perfect digestion, with no exceptional loss of nitrogenous material."

Lack of motility, or, as it is sometimes termed, gastric insufficience, on the contrary, causes vastly more serious disturbances of digestion and, consequently, of nutrition. This, resulting as it may either from a narrowing of the pyloric orifice or a lack of tonicity of the muscular coats of the stomach, allows the contents of the stomach to remain a much longer period than is customary in normal digestion, thereby causing fermentations which produce intensely acid material, gases of various kinds, and often even toxins, giving rise to all the symptoms associated with tetanus. In the more recent literature pertaining to this subject, numerous instances are given in which acute dilatation, which is only an increased degree of this condition, has produced death. As a rule, absorption and motile power of the stomach keep pace with its secretory powers. We have an instance, however, in the case of cancer of the stomach, in which, while the secretory power suffers most seriously, even to the absence of both pepsin and HCl, the motive power is increased to such a point that often exaggerated movements of the stomach are perceptible through the abdominal wall. The residue which is found in the stomach at the withdrawal of a test-meal is dependent upon three factors, *viz.*, the patency of the pylorus, motility, and absorption. In addition to this, we must also add a fourth factor, the activity of osmosis. It is well known that a constant osmosis takes place by which certain substances, such as sugar, peptone, etc., are absorbed by the stomach, while, on the contrary, there is a constant exudation of water into the stomach from the blood. This has no relation to the secretion of pepsin, HCl or rennin, but depends rather upon the nature of the substance taken as food. For instance, in these experiments it has been frequently noticed that the amount of fluid withdrawn from the stomach is much less after pure albuminous substance has been given, than when the albumin and carbohydrate have been given in the form of an Ewald meal. It can also be demonstrated that the water which is given in a test-meal is never withdrawn in its entirety, nor is it probable that the water found is identically the same as that given. We have an analogous circumstance in the increased urine resulting from drinking large quantities of water, when the water in this increased urine is evidently not the same as that which is drunk. Hence we may have different degrees of dilution of stomach-contents, according to the activity of osmosis. This renders quantitative determinations, of course, only relative. Another factor is our inability to be sure that all the contents are withdrawn from the stomach. Further, the removal through the py-

[1] From the Chemical Laboratory of Tufts College Medical School.

lorus may be hastened or retarded and absorption of the digestive products more or less rapid. If, as some investigators insist, the pylorus is not open until digestion is complete, it is an easy task to test the residue before the contents leave the stomach for the amount of albumose peptone left unabsorbed. According to other views, there may be a constant discharge of the liquid contents into the duodenum, solid particles remaining behind. Yet no digestion is ever complete, either artificial or stomachic, all the albumin may be in solution, there may be no albumin coagulable by heat, but we never fail to find some acid albumin. In contents which were withdrawn sixteen hours after food was taken, some acid albumin was found.

There exists a certain confusion between the term absorption and motility. Bouveret says, "If, after an Ewald meal, more than 40 cc. are withdrawn, it shows a slow absorption." Since water is so little or not at all absorbed, and the greater flow is always in the direction of the interior of the stomach, in experiments where the pylorus is closed by ligatures it is difficult to understand what the amount of fluid has to do with the absorption. It seems evident that this factor (the amount) must always be a test of motility and not of absorption. The residual albumose peptone may, however, be taken as a measure of this absorption, representing as it does that portion remaining in the stomach after an hour's interval. Our object now is with a certain definite amount of albuminous food to establish a normal residual albumose peptone one hour after the meal.

The rapid method for estimating this was given by the writer in the *Boston Medical and Surgical Journal*, Vol. CXLII., No. 10. At first an effort was made to prove connection between gastric insufficience and poor absorption. In two cases stomach contents were removed fifteen hours after eating. There was found in one .017 gram albumose peptone; in another as the result of four removals there were found respectively .184, .011, 0 and .200 gram. Then 37 cases were examined, some once, some several times. These were all given a test-meal and the contents were withdrawn at the usual interval of an hour. In every case, the residual albumose peptone was determined and expressed in grams. In all, the upper limit was taken as representing the least favorable absorption, since only that part unabsorbed is being estimated. When two or more examinations were made, the results were averaged and the average also given. The results of these 37 examinations appear in the following table:

						Average.

To determine a standard, if we arrange these results in order of the largest amounts of residual albumose peptone found, we have over 1 gram in 3 cases; between .8 and 1 gram in 1 case; between .6 and .8 gram in 3 cases; between .4 and .6 gram in 9 cases; between .2 and .4 gram in 12 cases; under .2 gram in 9 cases. From this we learn that .6 gram seems to be the limit beyond which absorption is delayed and impaired. It may be objected that in the lower limit, the results may as well be due to impaired digestion as improved absorption, but we learn in what follows that the digestive power of the gastric juice was always determined so that a decision between these two conditions can always be reached. If we take the average of the results where two or more examinations were made, we find that there is over 1 gram albumose peptone in 2 cases; between 8 and 1 gram in no case; between .6 and .8 gram in 2 cases; between .4 and .6 gram in 4 cases; between .2 and .4 gram in 17 cases; under .2 in 12 cases.

When we arrange the results in this way, we find that the greater number contained less than .4 gram of albumose peptone in the stomach at time of removal. As these cases were taken from the service of Dr. R. F. Chase, of the Boston Dispensary, to whom the writer's thanks are due, and were those in which mild gastric disturbances were complained of, they probably furnish a fairly satisfactory series from which to obtain results for future reference.

If, when increased quantity of fluid is withdrawn from the stomach, the albumose peptone remains the same, then the percentage must be lowered. If, on the contrary, an increased fluid content is accompanied by relative as well as absolute increase of residual peptone, then lack of absorption and impaired motility are associated. In urine, when we have largely increased amount

of fluid the percentage of solids is also diminished. Upon reference to our data, we find frequently associated increase of liquid and an increased percentage of albumose peptone. We have, for instance, the case of Lackay, with 250 cc. contents and 4.5 per m. of albumose peptone; J. G., with 102 cc. contents and 5.3 per m.; R. B., with 100 cc. contents and 6.6 per m.; E. B., with 132 cc. contents and 10.2 per m.; Album, with 95 cc. contents and 5.2 per m.; also the same with 200 cc. contents with 6.6 per m.; B. M., with 160 cc. contents and 4.6 per m. We have here unquestionably an association of diminished motility and impaired absorption. On the contrary, in two cases this law fails to apply—in Roland, with 200 and 125 cc. and 3.3 per m. in both, and H. L., with 145 cc. and 3.3 per m. These show that poor absorption is not always associated with lack of motility, but frequently is. With reference to the amount of HCl of those cases in which more than .600 gram albumose peptone was found, two had a lessened amount of HCl, four were normal, and one increased. In fact, there is no reason to believe that both conditions should be similarly affected, except that both are dependent upon nervous influence, and the result of shock, worry, etc., may be that of diminishing the flow of HCl, as well as retarding the absorption of the stomach.

Digestive power is necessarily dependent upon the secretory functions of the stomach, demanding at the same time pepsin and HCl or organic acids. But as the HCl is always determined we have a means of keeping a check upon the amount of pepsin present. If the HCl is normal, then the failure of digestive power must depend upon the lack of pepsin. The condition is rarely present, because pepsin is one of the most persistent ingredients of gastric juice. We must not lose sight of the fact that an excess of HCl may have an inhibitory action upon the action of pepsin. Experience shows that this is even more important than diminished HCl, for the latter deficiency can be made up by the presence of the volatile acids. The method for testing the digestive power of the stomach was given in the article in the *Boston Medical and Surgical Journal* to which reference has already been made. The factor used, so many parts per m., means that each gastric juice after digesting a requisite amount of albumin, contains so many parts of albumose peptone per m., less the amount it contained when withdrawn from the stomach; or, in other words, it was able to produce from native albumin so many parts per m. of its volume of albumose peptone. These results, with their average when more than one estimation was made, can be found in the following list:

							Average.

Upon reference to these results, we find that when the largest digestive power in each case is taken we have a degree of digestion greater than 7 parts per m. in 5 cases; between 5 and 7 parts per m. in 10 cases; between 3 and 5 parts per m. in 10 cases; between 1 and 3 parts per m. in 10 cases; under 1 part per m. in 1 case. Judging from the most numerous in each division, we are led to believe that this power of the secretive action of the stomach may vary anywhere from 1 to 7 parts per m. Above and below these figures, few cases occur. Upon referring to the average, where two or more examinations were made, we find that this power was 7 and over per m. in 2 cases; 5 to 7 per m. in 7 cases; 3 to 5 per m. in 13 cases; 1 to 3 per m. in 12 cases; below 1 per m. in 2 cases. Here the results are so narrowed that 1 to 5 parts per m. seem to include the majority of those cases examined. When the digestive power is a weak one and HCl is normal, there must be a lack of pepsin. There is an excellent illustration of this in the case of O'Neil, who had a total of HCl of 2.5 and 2.6 per m., with free acid, yet has only a digestive power of .6 and .3 of 1 part per m. Montague is another, with a total HCl of 2.3 per m. and a digestive power of only .3 per m. Unquestionably, we may also have cases where the amount of HCl is enough to inhibit the action of the pepsin. Album has an HCl of 3.9 per m., and a digestive power of only 1 per m. Cleaves, also, has an HCl of 3.1 per m., and a digestive power of only .3 per m. We have also the possibility that the amount of pepsin is limited and, if distributed through a large amount of fluid, the 10 cc. which were always taken for these tests would contain much less pepsin than a gastric content of lessened amount. We can see an illustration of this in the case of Levine,

with 145 cc. contents and 2 per m. digestive power; Roland, with 200 cc. contents and 1 per m. digestive power; Montague, with 160 cc. contents and .3 per m. digestive power; and Album, with 200 cc. contents and 1 per m. digestive power. Upon consideration of all the facts presented by these determinations, we may be allowed to arrive at the following conclusions: (1) No examination of the stomach is complete without testing its absorptive power. (2) The method herein employed, until a better one is devised, gives us as much information as any method extant. (3) Presumably, retardation of absorption does not occur with simple hypotony or gastric insufficience without dilatation. This may account for absorption being sometimes deficient and sometimes normal, with gastric insufficience. (4) In order to differentiate between a good absorption or a poor digestive power, the latter must always be tested.

THE NATURE TREATMENT OF TUBERCULOSIS.

By R. O. BEARD, M.D.,
OF MINNEAPOLIS, MINN.;
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF MINNESOTA.

There is no question of more dominant interest to-day to the profession of medicine, to the student of sanitary science or to the general public—which depends upon both for its enlightenment in matters of disease—than the question of the possible prevention and cure of tuberculosis and, especially, of tuberculosis in its pulmonary form. The importance of this question is growing with the public recognition of the prevalence and fatality of the white man's plague. Its solution is coming to be in the popular, as it has long been in the professional, mind a matter of urgent demand.

Perhaps nothing has contributed more to this awakening of the public consciousness to its own dangers from tuberculosis than the failure and the consequent disappointment which followed, some years ago, upon the introduction of Koch's tuberculin. "It is better to fail than never to have any striving that is worth being called a failure," for it is so often true that the mistakes of to-day are the stepping-stones to achievement on the morrow. Koch did more for the future control of tuberculosis than to discover the tubercle bacillus. He did more than to put into the hands of the medical world an agent of diagnosis which has proved and is destined to prove of inestimable value in the discovery of diseases in men and animals. If he overshot the therapeutic mark, he pointed to a target of treatment which men have since sighted with greater success. If he did not find a curative agent, he suggested a scientific method of dealing with disease in its use. If he did not solve the problem the solution of which we are still seeking and toward the solution of which so many other abortive attempts have been directed, he stimulated professional inquiry and aroused popular consciousness to the possibilities of relief.

In the world of science, as in that of commercial values, demand is the constant stimulus to supply. When human society learns the economic value of human life and appreciates its waste—in a single direction and by a single cause—to the proportion of ten per cent. of its total, it will not be long before it writes an equation in which the third factor to be found by the sanatarian will be that of cure. And that we are several steps nearer to the finding of that required factor is largely due to the generally discredited labors, as well as to the earlier accredited discoveries, of Robert Koch.

The indications of the growth of this popular professional demand are everywhere manifest. They are seen in the enactment of ordinances in our great cities prohibiting expectoration in public conveyances and, in some notable instances, requiring the report of cases of pulmonary consumption to the health authorities. They are manifested in the publication of popular tracts and official directions concerning the avoidance of contagion and the destruction of diseased sputum. They are seen in the actual agitation, in a great commonwealth, of popular sentiment for the quarantine of a whole State against tuberculous pilgrims in search of climatic relief. They are seen in the organization, in several States of the Union, of societies for the prevention of tuberculosis. They are read in the formula of the objects of these bodies, well illustrated by the constitution of the Illinois Society, which is "to educate public opinion in the doctrine of the contagiousness of the disease, to instruct the public in practical methods of avoidance and prevention, to visit the consumptive poor and supply them with the necessary materials with which to protect themselves against the disease, to furnish them with hospital treatment, to cooperate with boards of health in preventive measures, to advocate the enactment of preventive laws and to establish branch societies throughout the State."

They are seen in the establishment of sanatoria and hospitals for the exclusive care of consumptives in certain of our big cities. They are shown in the special precautions which are being taken for the isolation of tuberculous patients among the inmates of insane asylums, schools for defectives, and penal institutions.

They have been evidenced within the past few months, by the assembly at the city of Berlin of an International Tuberculosis Congress, which was conducted with success—a success which is none the less important because it is rather popular than professional in its results. That success lies, not in the discovery or announcement of new facts or principles, but in the organization of agencies by which these known facts and principles may be applied. It means, as an operative influence, no especial stimulus to that patient effort of the pathologist, the clinician and the sanitary scientist which still goes on unceas-

ingly, but a stimulus to the practical employment of those means and measures which are the birth of the pathologic and sanitary science of to-day.

And, finally, these indications of a popular and professional demand for a realization of results are seen in the proposed or accomplished dedication of large tracts of land and forest and lake, as great public parks for the sake, among other desirable ends, of their preventive and remedial possibilities as great national or provincial health resorts.

All of these activities have been inspired primarily by the study of the etiology and course of the disease which has been going on, since the day of Koch's initial discovery, in the laboratories of pathology and bacteriology throughout the scientific world. This study of the warfare which is waged between the human tissue-cells and the bacillus tuberculosis has taught us and is teaching us, more and more forcibly, the practical lesson that the task of the public sanitarian and the physician is largely one of prevention, and that cure—a secondary and short-lived possibility in the course of the disease—is best to be accomplished by extending the principles and methods of prevention to the assistance of the tissue-cells in their life and death conflict with the disease. It means, on the one hand, to make the conditions of human life as favorable as may be for the integrity of the tissue-cells and as uncomfortable as possible for the tubercle bacillus. It means, on the other hand, to make the selfsame conditions of human life which will sustain that integrity operative for its restoration under attack. It means something in the way of hope for the future, when the statistics of human health in the large cities, even of the Northwest, show a phenomenally low death-rate, and when we learn from the lips of Minnesota bacteriologists that, in this region, their germ cultures have a provoking tendency to die out. In the adjustment of these two tendencies to each other we may obtain demonstration of the possibilities which hygienic measures afford for the maintenance or recovery of resistance upon the part of the tissue-cells to disease.

Strange, is it not, how intuitive is the quality of ideas which spring into action before the reason for their existence can be discovered! Modern science recquips the old hypothetic notion of the *vis medicatrix naturae* with the dignity of a demonstrable fact; and that fact gives us the impetus to the most hopeful movement of modern medicine toward what may be fitly termed the Nature treatment of tuberculosis.

There is nothing new in the isolated facts which enter into this, nevertheless, novel conception. No new principles were announced at the International Congress of Berlin, and yet the consummate value of the deliberations of that Congress lay in the recognition of a new system of treatment into which old facts fit and in the elaboration of methods by which that system can be practically employed. With a good understanding of these old facts we have been slow—as a child piecing his newly-learned letters into words—to compose them into the lesson that they teach. Long have many isolated cases of cure pointed out to us the advantages of some element of climate in the treatment of this prevalent disease. Long have we sought in differences of altitude and temperature and moisture for the key to these effects, while empiricism has dictated to us the advantages of this or that locality as an agency of cure. Out of their fortunate experiences, physicians have learned to extol the virtues of the Adirondacks of New York, of the Blue Mountains of North Carolina, of the forests of Ontario and New Hampshire, of the high altitudes of Colorado and New Mexico, of the dry, sand-swept plains of Arizona where decomposition is merely desiccation, of the warm, dry air of Texas and California, and even of the cold, dry air of Minnesota.

But only now, as the International Tuberculosis Congress of Berlin declared, are we learning that but two prime factors enter into the qualities of all these favorable regions, but two elements are essential in their curative or preventive qualities. These factors are purity and dryness of atmosphere, in whatever latitude, at whatever altitude, on plain or mountain, in forest or on ranch. The conclusion is a simple but potent one. It means a new emphasis upon the pernicious influences of the overcrowded quarters of our great cities. It means the necessity for a new development of suburban dwellings for the poor. It means the essential isolation of consumptives who pollute the atmosphere their neighbors breathe. It means a desirable reversion from urban to rural life. It means the establishment of sanatoria which shall afford sufficient cubic space for the diminished cubic area of tuberculous lungs. It means—it should mean—the segregation of lands in large tracts where these ideal qualities of atmosphere exist, where these qualities can be preserved and where they can be utilized for the conservation of the health of those who are well and the restoration of those who are diseased. It is not remarkable that the cities of California and Texas are beginning to blacklist consumptives. It is time they did. A quarantine against tuberculosis in our towns should be as effective as a quarantine against Yellow Jack.

The aggregation of disease-germs is dangerous anywhere, even though the atmospheric qualities of a given locality may be unfavorable to their development. Mass the tubercle bacillus anywhere and it will, sooner or later, work its destroying way. Disease-germs should be subjected to atmospheric dilution. Give them sufficient cubic area of pure, dry air and their most effective cultures will die out as they do in the laboratories of Minnesota. Put the tuberculous patient into the vastnesses of the pine forests of our Northwest and his cultures of the bacillus may not thrive.

New York has learned the lesson, and learned it expensively late, in the reservation of the

Adirondacks. Ontario has learned it in the segregation of the Algonquin Park. Minnesota is trying to put that lesson into practice by the enterprising initiative of her medical profession, by the public-spirited aid of her associated women's organizations, by the assistance of her Nature-loving friends in other States—in her effort to secure the creation of a great National Park in her pine forests and among the multitudinous lakes of the North. The health idea inspired and stands back of this project. To make this last great tract of native pine forest a national health resort, a natural sanatorium, is the primary and the most urgent argument for its segregation.

Other arguments obtain. In fact, no single public project carries with it more variant and cogent reasons for its success. Forest reservation is an economic necessity. The ruthless ax of the lumberman and the fire which follows in his destroying footsteps have almost completely removed from the face of this continent its vast areas of native trees. Forest culture has demonstrated its paying quality in European states. An object lesson in this science is needed in America. The forests of these Minnesota reservations can be made more profitable by tree culture than by agriculture.

The conservation of the Mississippi water supply in the matter of quality and distribution is a motive. The great natural sponge which the soil of the native forests forms acts at one and the same time as a vast filter and a vast reservoir. The artificial reservoirs which the Government has constructed at the headwaters of the Mississippi at an expenditure of millions of money, are less effective by far in the control of freshets and the distribution of the waters of the great valley than this native forest sponge.

The preservation of the indigenous game of this game-stocked region is a secondary reason. No more delightful sportsman's paradise can anywhere be found than its woods and lakes afford.

The salvation to posterity of this great park is another and a nobler motive. The lover of Nature needs but to see the beauties of these primeval pines and of these great inland lakes to feel that their final destruction would be a permanent loss to the higher life of the people.

But of more momentous consequence, of greater economic weight is the argument for the segregation of this area for sanitary purposes. Its opportunities are in therapeutic demand. The value of human life, not merely to the individual who possesses it, but to the State, far outreaches any measure of material wealth. The Nature treatment of tuberculosis in this available region will repay the nation in men more than it can gain in timber by its destruction or in navigation by its saving.

The sanitarians of this continent may exercise a large influence in determining the balance of public opinion in favor of the creation of the Minnesota Park. The American Public Health Association has already recorded its approval of the project. It should lend the weight of the personal influence of its members to the accomplishment of this end.

But while the question of climate, the quality of pure dry air, to be attained best by the preservation of such vast tracts of favorably conditioned land, is a large one in the Nature treatment of tuberculosis, it is not the only significant one.

The medical world is indebted to Dr. Walther of Nordrach, in the Black Forest of Germany, for an object lesson in this Nature treatment, for a demonstration of the results of a judicious combination, with favorable climate, of other important hygienic conditions.

The principle of as nearly physiologic rest as may be attained is of major importance. The influence of this factor in the treatment of tuberculosis was of common observation in the confinement of patients undergoing treatment, some years ago, with Koch's lymph. Hyperpyrexia is an invariable indication for complete repose. After its subsidence, the principle of carefully graduated exercise is of moment. By this method, the powers of the patient are systematically developed until they will endure sustained labor or excursions of from five miles to ten miles on foot.

And, finally, the principle of forced feeding, as to quantity, with due respect to the physiologic intervals of digestive repose, is a factor in the method. The gradual but material increase of food supplies is well endured, even in advanced cases and appears to go far in advancing the nutritive conditions of the tissues. If recent investigations into the relations of the leucocytes as primary agents in food absorption and elaboration give us a safe guide to follow, we may be better able to understand how forced feeding enhances their phagocytic power.

This, in a few words, covers the essential principles of what is fitly termed—the Nature treatment of tuberculosis. If, severally, its facts are not new, in their association they are of added weight and larger hope for the control of this most prevalent and destructive of the diseases of civilization.

MEDICAL PROGRESS.

Mortality from Diabetes Mellitus.—The 202 deaths from diabetes which occurred in the city of New York during 1899 have been classified by H. Stern (*Med. Rec.*, Nov. 17, 1900) to show the sex, age, nationality, complications, etc. The sex seemed to have no influence and the deaths were distributed about equally over the different seasons. The greatest mortality occurred between the fifty-fifth and sixty-fifth years, and diminished rapidly toward the end and beginning of life. Fifty-seven were born in Germany, 51 in United States and 37 in Ireland. It was es-

timated that at least 54 or 25 per cent. were Jews and 51 were Irish. Mental exertion, characteristic modes of living, gluttony, alcoholic intoxication, etc., are given as predisposing factors in causing diabetes more often in these races, but the potent influence is believed to be the breeding in and in to which the Jewish and Irish races still adhere. It has been supposed that diabetes mellitus is especially frequent among the well-to-do, but these statistics seem to indicate that it occurs in greater frequency among the working people among whom gluttony and leisure hours are exceptions. Coma is given as the direct cause of death in 60 cases, but undoubtedly pure diabetic coma occurred in a much smaller number. Gangrene was the most frequent complication and appeared in the foot or leg in 32 cases. Other frequent complications were septicemia, phthisis, nephritis, and cardiac dilatation.

Suprarenal Extract.—Another favorable report is made upon the action of the suprarenal extract in diseases of the respiratory tract. P. Floersheim (*Med. Rec.*, Nov. 17, 1900) has used it in rhinitis, acute tracheobronchitis, chronic bronchitis, congestion and edema of the lungs, hemoptysis and pulmonary tuberculosis. Its action in diseases of the upper tubes is more certain and the sensations of dryness, tightness and rawness are relieved, but acute bronchitis when treated from the onset was usually cured in twenty-four hours. The beneficial action obtained in congestion and edema of the lungs was undoubtedly due, not only to the constricting action upon the blood-vessels, but also to the stimulating effect upon the heart. Apparently good results were obtained in cases of hemoptyses, but it is, of course, speculative how much benefit was due to this drug. The powder is administered in three-grain capsules, chewed without water and swallowed in a few minutes. When the doses are sufficiently large the action is apparent in from two to fifteen minutes. In some cases the action of the drug is permanent, but in the majority of cases it lasts only from ten minutes to an hour and must be frequently repeated.

Meralgia Paresthetica.—This syndrome is the result of some functional or pathological change in the external cutaneous nerve, characterized by sensory disturbances of the anteroexternal surface of the thigh. Pain and paresthesia may, however, go beyond the zone of distribution of that nerve, but in the majority of cases only one branch is affected. A. Gordon (*N. Y. Med. Jour.*, Nov. 17, 1900) reports a case in which the condition came on after typhoid, and being peculiar from the fact that both the anterior and posterior branches were effected and at least one branch of the anterior crural. It also presented a phenomenon called intermittent lameness and described by Charcot as "claudication intermittente." Charcot's cases were characterized by severe pain and numbness of both legs when an attempt was made to walk, due to an arteriosclerosis which prevented proper nutrition during extra exertion. This case, however, showed no arterial changes and the pain was explained by the supposition that the psoas muscle when contracting aggravated the pains induced by the neuritis in the nerve lying on its surface. Electricity, massage, and potassium iodide are recommended, but are of very little service. The removal of a large portion of the external cutaneous nerve is the only rational and permanently successful mode of treating the genuine cases of meralgia paresthetica.

Serum Reaction in Fetal and Infantile Typhoid.—In a recent paper by Dr. John L. Morse (*Journ. Boston Society of Med. Sciences*, Oct. 16, 1900) this very interesting subject has received further consideration. The conclusions enunciated agree in the main with the facts already presented in scattered articles. From the article the following points may be gathered: The serum reaction occurs in infantile as in adult typhoid. As to whether or not it occurs in fetal typhoid the author has not been able to find any data bearing on this side of the question. The agglutinating power may or may not be present in the blood of infants born of women with typhoid. If present it is transmitted through the placenta. The author conceives the possibility of the formation of the agglutinating principle within the child in response to toxic principle transmitted from the typhoid mother. The agglutinating principle may pass through the normal placenta; part of it, however, is arrested in the passage. The conditions determining its transmission appear to depend on the strength of the agglutinating power of the maternal blood, and the length of time during which the placenta is exposed to it. Other observations show that it may be transmitted through the milk, sometimes appearing as soon as twenty-four hours. In the maternal blood in such cases the reaction is strongest; the agglutinating power of the milk is stronger than that of the nursling. This weakening is due to resistance to passage of the principle by the mammary gland and the nursling's digestive tract. The chief factors governing transmission appear to be the intensity of the agglutinating capacity in the maternal blood and some unknown condition in the digestive tract.

Pelvic Symphysitis.—A. Noto (*La Riforma Medica*, Nos. 177-179, 1900) records the history of two cases occurring in his own practice, which, with the thirteen other cases recorded since 1778, constitute all that is known of this rare disease. Case I.: A woman, aged thirty-eight years, whose previous history as to heredity, menstruation, and five previous pregnancies, was normal; two days after the delivery of her last child had a rise of temperature preceded by a violent chill; these phenomena appeared regularly for nine days without intermission and without discover-

able cause; death occurred on the tenth day; autopsy revealed nothing peculiar except the presence of pus at the symphysis pubis; the cartilage was eroded, exposing the bare bone. Case II.: A woman, aged thirty-nine years, who had had nine previous normal pregnancies and whose previous personal history was negative, three days after the birth of last child began to have chills and fever, which continued daily unabated, the lochia becoming by the eighth day extremely offensive; for this she sought hospital treatment; on her admission, examination was negative except that over the mons veneris a tumefaction was noted with all the manifestations of an acute inflammatory process, the pain being quite prominent; after incising, cleansing and draining this tumor over the symphysis, all of the acute symptoms subsided and the patient made an uninterrupted recovery. The author's conclusions are as follows: During pregnancy the affection comes on without cause, but is preceded by the relaxation of the joints involved in the gravid state; this physiological state may, if aggravated, become pathological; then standing is painful; the disease is usually caused by traumata during labor, when there is a disproportion between the pelvis and the fetal head; the active cause is the presence of a pyogenic germ within the joint giving rise to a general septicemia or pyemia; the symptoms generally appear a few days after labor, and are characterized by chills, fever, and general rapid prostration with but little external manifestation of the involvement of the symphysis pubis joint, until the process has become more advanced; then swelling and all the symptoms of an acute local joint trouble are manifest; usually as a result of this the cartilages are eroded and the bone surfaces bare. Occasionally the tumefaction becomes less circumscribed and a diffuse infiltration occurs, involving the abdominal muscle-sheaths or extending down into the labia, pain radiating toward the thighs or to the nates. The prognosis should be guarded, for the course of the disease is slow as regards recovery, and relief is to be had only by prompt, efficient, and thorough surgical intervention. Absolute rest must be insisted upon during a somewhat tardy convalescence. Supporting tonic treatment is also indicated.

Pulmonary Emphysema and Nasal Occlusion.—L. Bullara (*La Riforma Medica*, Nos. 183-184, 1900) deduces the following conclusions from experiments upon dogs. Complete occlusion of the nares produces emphysema in a few days and changes the respiratory rhythm, the frequency of respiration being decreased and the depth of respirations being increased. A smaller quantity of air enters the lungs when the animals breathe only through the mouth than when the nose is used in respiration; hence it is fair to conclude that when nares were occluded the dogs were forced to take deeper inspirations in order to compensate for the diminished volume of air entering the lungs; pulmonary emphysema, therefore, depends upon the increased volume of respired air, a purely mechanical result of occlusion of the nares.

Functions of Cerebellum.—R. Gatta (*La Riforma Medica*, Nos. 181-182, 1900) as a result of extended experimental observation on animals concludes that (1) the clinical syndrome of cerebellar disease is rendered multiform by the phenomena of compression and irritation of the contiguous and distant parts of the brain (the pons, medulla, cranial nerves and cerebrum); (2) the alterations in the cerebellum and the clinical and experimental phenomena are in proportion to the extent of the lesion; (3) complete destruction of the cerebellum in animals and similar lesions in clinical cases produce ataxia, asthenia, and atony; these effects remain for a long time in the experimental cases, although the functions return to a certain extent in some cases; (4) the pathological experimental processes, resulting from rapid intoxication, may occasion disease lasting months and years; (5) clinical observations are in accord with the results obtained experimentally.

Face Presentations.—O. Schaeffer (*Centralbl. f. Gynackol.*, Oct. 27, 1900) concludes that, as a rule, when the parturient canal is normal the forceps are usually contraindicated, both as a correcting and as a traction instrument in difficult face and brow presentations. Occasionally when the head is small and the occiput short or when the head is freely movable upon the trunk, they may in skilled hands and normal path of delivery serve to save a child otherwise lost. Force should never be applied. When the head is less movable, fixed manual correction after the method of Rose or Volland should be tried. The same observations apply to anterofrontal presentations with advance of the brow even in normal canals when mere bettering in the presentation is at stake. Finally, attention is directed to the fact that forcible traction along with the local mechanical extension and squeezing may set up long and severe nervous reflex phenomena.

Retrenchment of Lipomatous Abdominal Wall.—J. B. Bullitt (*Annals of Surgery*, Nov., 1900) reports a case of very large umbilical hernia in a fat person whose abdominal wall was four inches thick in fat alone. He approached the neck of the sac through a horizontal incision about three inches above it. After the usual steps for radical cure had been taken, the incision was extended to eack flank where it was joined by another lower down. The interval between the two comprised several pounds of fat which were ablated. The wound was drawn together by buried continuous catgut, deep interrupted silkworm-gut retention, and, finally, catgut buttonhole sutures. Primary union in a scar twenty-two inches long and four inches deep, with cure of the hernia, resulted. The pendulousness of the abdomen was largely removed, although a still greater segment could safely have been taken.

THERAPEUTIC HINTS.

Electricity to Remove Hair.—Léo Leistikow uses the platinum-iridium needle with Behrend's needle-holder, in which contact is broken by pressure on a stylet. The anode is placed in one hand of the patient and the needle introduced into the follicle in the direction of the hair, a current of 2 to 3 milliampères is kept on for 20 to 30 seconds, the needle withdrawn, and the hair pulled out with epilating forceps. Warm, moist compresses diminish the inflammatory reaction. While introducing and removing the needle, the current must be broken, or it causes pain and involuntary muscular contractions. The needle must be carried along the hair to the base of the follicle, or the hair will return. The procedure is very easy and effective.—*Monats. für prak. Dermatol.*

Fungous Diseases of the Skin.—The radical cure, writes P. G. Unna, of the true saprophytes of the corneous layer, as in erythrasma, and pityriasis versicolor, and of the hair, as piedra, leptothrix, and trichorrhexis nodosa, by the ordinary fungicides, such as mercury, sulphur, chrysarobin, tar, and iodine, is extraordinarily difficult. Mechanical methods (shaving, exfoliation, epilation, and pitch-plasters) have been used with moderate success. After much experimentation the author has found a chemical method at once mild and effective. He paints the affected area once a day for 3 or 4 days with:

℞ Paraform .....
Ether .....aa. 2.0 (gr. xxx)
Collod. flex.....16.0 (℥ss)

In generalized pityriasis versicolor, bands the width of the hand are successively painted and after 2 or 3 days rubbed with vaseline or zinc ointment until the scales are removed. By this means the whole body is cleaned in about 15 days. As an aid in the treatment Unna gives a daily wash with a superfatted soap containing 2 per cent. of formaldehyd.—*Monats. für praktische Dermatol.*

Ether for Sebaceous Cysts.—Emile Sergent uses Vidal's method of injecting ether until the cyst is distended. The needle being left *in situ*, some of the ether with dissolved sebaceous matter runs out. Then more ether is injected, and the process repeated until fluctuation is apparent, and a brownish crust appears around the needle entrance. The contents may then be readily expressed by opening up the tract with a stylet, and the empty sac removed through a comparatively small opening. The operation is bloodless, painless, without danger, and it leaves no disfiguring cicatrix. A small fibrous cyst with very little sebaceous matter is not likely to be benefited.—*La Presse médicale.*

Asthma.—Nothing is so likely to induce an attack, say Fowler and Godlee, as retiring before digestion is finished, therefore the principal meal should be taken at midday. Alcoholic drinks and coffee can rarely be taken safely. To ward off attacks, iodide of potassium, gram 0.3 (gr. v) t. i. d., increased rapidly to gram 4.0 (℥i) a day, has been of most service, and to this may be added the ethereal tincture of lobelia, gram 1.3 (℥ xx), or extract of stramonium, gram 0.015 (gr. ¼). Arsenic is worthy of trial, but is of less value. Some patients never retire without burning niter paper, made by saturating blotting-paper with a 1-in-16 solution of potassium nitrate, or smoking a cigarette containing stramonium or some such remedy. As regards locality, every asthmatic is a law to himself; most find that in the smoky atmosphere of a large town they are more free from attacks than elsewhere. If chronic bronchitis is the cause, a warm, dry climate, avoidance of exposure to cold and damp, and cod-liver oil are indicated. When the nervous factor predominates, with slight catarrh or emphysema, a high altitude is usually preferred. Inhalation under pressure of a hot, dense vapor, as at Mont Doré, is often of benefit. When a gouty factor is present, colchicum and alkalies are indicated, and mercury and saline purgatives in constipation and functional derangements of the liver. In some persons these latter are certain precursors of an attack. Morbid conditions of the nasopharynx require local or climatic treatment.—*Diseases of the Lungs.*

Exophthalmic Goiter.—M. A. Starr recommends rest, careful diet, and glycerophosphate of soda, gram 1.0 (gr. xv) three or four times a day, to counteract the poison in the blood. Mercury inunctions to the neck, especially of the red iodide, tincture of iodine, gram 0.3 (℥ v) t. i. d., and belladonna, are sometimes of use. Iron and arsenic may be administered as tonics. Injections of iodine and other irritants are dangerous, and digitalis, strophanthus, and counterirritation are of little use. When pressure symptoms arise from the enlarged thyroid, partial extirpation must be performed.

Scabies.—To avoid the irritating action of the ordinary remedies for itch in children, Léon Perrin rubs the whole body at night with

℞ Camphor oil of chamom. 100.0 (℥iijss)
Ointment of liq. styr... 20.0 (℥v)
Balsam of Peru..... 5.0 (grs. lxxv)

The next morning wash with soap and hot water, and powder the skin with starch. If the skin is a little inflamed apply zinc-oxide ointment. The first night the itching ceases, and in eight or ten days the cure is complete. To avoid recurrence all the clothes and bedding must be washed with disinfectants.—*Journal de Médecine de Bordeaux.*

Insomnia of Alcoholism.—For patients suffering with acute alcoholic delirium or alcoholic mania, Dr. D. R. Brown recommends:

℞ Chloralamid ..... 1.0 (gr. xv)
Hyoscin hydrobrom. 0.0006 (gr. 1/100)

—*Trans. Seventh International Congress on the Abuse of Alcohol.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, NOVEMBER 24, 1900.

NEW YORK AND ITS WATER SUPPLY.

In a municipality of the size and importance of New York City it is incumbent upon the authorities to provide for its citizens a good water supply. It is not enough that the water should be free from *materies morbi* capable of producing disease, but such water should be palatable, free from taste and odor and sufficient to meet the demands of modern civilization.

For the past three weeks the water of the Borough of Manhattan has not been up to its usual excellent standard. Different sections of the city have been affected in different manner, but there has been an almost universal complaint of turbid water with a decidedly disagreeable "fishy" or "oily" taste. The weekly reports of the Health Department have not shown that there are any unusual contaminations that might render the water unsafe to the consumer and there are no reports of illness that are directly traceable to it. The question seems to resolve itself into purely a "matter of taste."

The subject of tastes and odors in water supplies is one that has engaged the attention of many investigators. Early observers ascribed disagreeable tastes to the presence of products of decomposition, but of recent years it has been recognized that the distasteful elements are due not to the dead, but to the living organisms that grow in most water supplies. Certain minute plants and animals growing in exceedingly large numbers are the offenders. Among these certain diatoms, as well as some of the other algæ, and a few of the lower animals develop in their protoplasm, as processes of their life activity, certain oils, which are closely related to many aromatic compounds of higher plants.

The Medical News has had some examinations made to determine, if possible, the causes of the present unpleasant conditions of the local water supply. The evidence submitted shows that there are no unusual factors in the present problem. Algæ similar to those which caused the unpleasant conditions of the Brooklyn water supply two summers ago have been found in numbers far exceeding the usual ratio. The most reprehensible of these are *Asterionella formosa*, *Melosira varians*, *Coelcospherium* and *Anabaena*. *Melosira* and *Coelcospherium* are especially abundant. Both of these last named organisms are known to develop odors and taste, the former, oily, the latter, sweet and grassy. *Asterionella* is usually credited with a distinctly fishy and disagreeable odor. The causes, therefore, of the present conditions are probably these algæ, which in varying proportions give the peculiar character to the water. The unusually warm fall may account in some measure for their excessive development, or, perhaps, the diminished amount of water stored in the reservoir. Opening up of mains may be in part responsible. Cold weather will probably cause their diminution, if not their disappearance.

Boiling the water will be of little or no service. The oils will be thereby only more thoroughly commingled with the water. Filtration may remove a few of the organisms, but not dispose of their oils. The only thing to do is to wait. Time is necessary to determine the causes of the unusual development of these organisms and give the key to prophylaxis. It may further be asserted that there is nothing harmful in the water supply, although a draught of cold water does not now possess its old-time associations.

TUBERCULOSIS IN TAILORS.

The fact that tuberculosis is extremely prevalent among tailors, especially the cutters, has long been well known and of great interest to clinicians. The sedentary nature of the occupation and the crowding which as a rule prevails in the

workrooms have usually been held responsible for this unusual prevalence. Recent observations, however, seem to discredit in part such etiologic factors in this connection. It has often enough been shown that individuals following other trades, but living under equally crowded conditions, may show comparatively a much greater insusceptibility. Observations of this kind have led many to believe that the high tribute paid to tuberculosis is referable to other factors than solely to overcrowding.

Repeated investigations of the local conditions lead to the conclusions that direct contamination by infected sputum constitutes the most menacing factor in its spread.

In support of this conclusion attention may be called to the fact that in all tailoring establishments, if much work is going on, there is a fine but noticeable dust present in the workroom consisting chiefly of the minute particles of the woolen clippings. The clippings themselves are thrown into barrels, there to remain for a few days until these are full, when they are thrown into bins or large receptacles placed not far away. They are left here, as a rule, for a few weeks until sold and taken away to be woven into what is known as "shoddy." This in turn is sold to dealers handling inferior grades of cloth or goes back to the original merchant as a second-rate article. Before it is resold, however, it is dyed. If this dyeing process is germicidal existing tubercle bacilli in the "shoddy" will be exterminated and the cutters who handle it will not be subjected to infection. If, however, the dyeing process does not kill the organisms, there is thus afforded a means of infection, if the original scraps were primarily contaminated. That this is the case seems undoubted, for the following reason: In tailors' shops, as in most other places, cuspidores are provided, the employers and managers particularly requesting that they be used; as a matter of fact they are largely neglected, while the barrels and the contents of the same receive the expectorations. When it is remembered that in these places as in all large factories there are usually some tuberculous employees, generally, although not always, in the early and undetected stages of the disease, a clear chain of evidence is established, provided that the dyeing of the goods does not destroy the tubercle bacilli.

Even if the organisms are thus rendered innocuous, there still remains a certain and evident means of infection in the contaminated contents of the barrels and bins, since, the sputum being dry, the emptying of the clippings into the bin itself or into intermediate receptacles permits of a thorough dissemination throughout the room. Again, the removal from the bins at a later date necessitates a still further shaking up and the liberation of untold numbers of minute particles of infected wool. The same barrels after being emptied are used and used again, and it is evident that, no matter what precautions for health have been taken in the surroundings of the workroom, they must still be dens of infection as long as surreptitious expectoration into the barrels takes place, as it undeniably does. The men disobey the requests of their superiors and are not cognizant of the gravity of their action.

It would seem that this matter is a suitable one for the interference of our vigilant Board of Health. The remedy, of course, lies in the proper use of cuspidores, but in view of human frailty and the close proximity of convenient barrels we must rely upon proper sterilization of the clippings. If this is impossible for commercial reasons, then it would seem that they should be destroyed.

PRIMARY SPLENOMEGALY.

Under various names—primary splenomegaly, primary epithelioma, and endothelioma of the spleen—has been described a most remarkable disease characterized clinically by a slow, progressive enlargement of the spleen, beginning in childhood, followed by an increase in the size of the liver. Concomitant with these changes will be found a simple anemia.

Since the thesis of Gaucher nearly two decades ago the condition has passed almost unnoticed. Until the appearance of a recent paper by Bovaird (*American Jour. Med. Sci.*, Oct., 1900) no systematic clinical and pathological study has been made by the half dozen or less observers who have written on this subject. From his own careful studies of two cases in children taken in connection with those already published, this author has been able to give us a fairly definite clinical picture which may serve in the recognition of this interesting condition.

From the facts at hand it is clear that the etiological factors are far from being clearly understood. The affection begins insidiously without fever; attention is first fixed upon the increasing splenic tumor and simple anemia. Later the liver becomes enlarged, and in some cases as

those reported by Bovaird slight enlargement of the superficial lymph-nodes may occur. Certainly if any conclusions are to be based upon the cases already reported the prognosis is to be regarded as unfavorable, although the course of the disease may cover many years.

The general resemblance of such cases to those of splenic anemia has been noted. The age of the patients, or better, the age of the patients at the beginning of the splenic enlargement; the persistent progressive character of the malady; the chronicity of the affection; the enlargement of the liver; the huge size of the spleen; the familiar distribution—all these are considerations of the highest diagnostic significance in the differentiation of the affection from the so-called splenic anemia of adults. Some cases grouped under the latter head may possibly have been primary splenomegaly; post-mortem investigation alone will be found necessary to make clear the real nature of the trouble in many instances.

Few subjects in pathology possess the same real interest which centers around the microscopical findings in the organs removed from these cases. The extensive endothelial hyperplasia observed in the spleen and to a less extent in the lymph-nodes and liver has already brought forward some discussion. All the writers thus far, with the exception of Bovaird, have either regarded the lesion epithelioma, carcinoma or endothelioma. But if we accept the definition of a tumor as an autonomous growth as laid down by Thoma then we cannot, as Bovaird very rightly points out, regard these cases of endothelial splenomegaly as instances of tumor growth. The evidence, moreover, scarcely admits the interpretation as metastases of the proliferative changes in the lymph-nodes and liver.

It is not at all unlikely that further investigation may show the infectious origin of these cases.

ECHOES AND NEWS.

NEW YORK.

Why Gouverneur Hospital is Slow in Building.—There has been considerable criticism because of the delay in opening the new Gouverneur Hospital, the construction of which began five years ago. It has been explained that the law requires that all the furniture for the hospital shall be made in the State's prisons and the prisons have been slow in fulfilling their contracts.

Typhoid in Upper New York.—Press dispatches report that typhoid is common in a very severe form throughout the north end of Manhattan Borough, as well as the Bronx. Uptown hospitals continue to take care of more than their usual quota of cases, but the mortality is not high. Thus far the MEDICAL NEWS has been unable to substantiate the press reports.

New York Pathological Society.—In the death of Dr. Lewis Albert Sayre the New York Pathological Society loses the last of the members who brought it into existence. The first meeting of the Society was held in Dr. Sayre's office on June 14, 1844, Drs. George A. Peters and Middleton Goldsmith participating in the formation of the new society. Dr. Sayre kept his interest in the society alive, occasionally attending its meetings, until the end of his professional activity. It is with a special sense of loss that the Society sees fade from its list of active members this illustrious name, enrolled at its first meeting when "the oldest pathological society in the world," as he was fond of saying, was created.

The New York Pathological Society now records upon its minutes the death of Dr. Lewis Albert Sayre, and adopts the following resolution:

Resolved, That the sympathy of the New York Pathological Society be extended to the family of Dr. Sayre in their bereavement, and that the above testimonial be published in the current medical periodicals.

(Signed) W. P. NORTHRUP, M.D.,
JAMES EWING, M.D.,
E. K. DUNHAM, M.D.

Charitable Bequests.—By the will of Abraham Wolff the following institutions were benefited: Hebrew Benevolent and Orphan Asylum Society of New York, $5000; the Home for Aged and Infirm Hebrews of the City of New York, $5000; Mount Sinai Hospital, $1000; the Montefiore Home for Chronic Invalids, $1000; the Society for Preventing Cruelty to Children, $1000; the Colored Orphan Asylum, $1000; the Hebrew Technical Institute of New York City, $2500; the Educational Alliance of New York, $3000; the German Hospital of New York, $1000; the Hebrew Infant Asylum, $1000; the Children's Aid Society, $1000; the New York Cancer Hospital, $5000; the United Hebrew Charities of New York City, $10,000; the Edenkoben Hospital in Germany, $2500.

Tenements and Tuberculosis.—The Tenement-House Commission held its first public hearing in New York City at the United Charities building, Twenty-second Street and Fourth Avenue, last Tuesday. The subject under discussion was "The Relation of Tuberculosis to the Tenement-House Problem." It was the unanimous sentiment of the speakers that with the proper kind of tenement-houses, houses which would make it possible for the tenants to get plenty of sunlight and air and to keep clean, and with the proper supervision and care by the City of those afflicted with the disease, tuberculosis could event-

ually be entirely stamped out. Dr. John H. Pryor of Buffalo, who was chairman of a committee to investigate tenement-house evils in that city, said that in Manhattan alone there were constantly 20,000 persons suffering from tuberculosis of the lungs in its various stages. In his opinion the majority of tenement-house dwellers had some form of tuberculosis. One reason for its great prevalence was that no proper care was taken of the victims. There were accommodations for 1000, whereas 20,000 had the disease. The result was that the infection constantly spread. He said it was the only disease which did not receive proper care.

"The disease is curable," Dr. Pryor declared. "People die of it because they are poor. That's putting it bluntly, but it's true. If they had the means to get away in the early stages of the disease and get proper treatment they would get well. The public has come to look on the disease as hereditary. This is not true. There are but two cases on record where it has been transmitted in this way. The tendency may be transmitted, the inability to resist it readily, but not the disease. Six thousand persons die yearly in New York of tuberculosis of the lungs. This could be checked very readily if officials had the power to change conditions in the tenements and put the afflicted people where they could be cared for." Dr. Pryor favored making it compulsory that every occupant of a tenement have 600 cubic feet of air, that no tenement be allowed to be built on a 25-foot lot and that the people should be educated as to how to prevent infection.

Dr. Herman M. Biggs, of the Health Department, presented maps of various tenement house blocks showing the prevalence of tuberculosis in certain infected and insanitary houses. He said that the death-rate from tuberculosis had been decreasing owing to the improvement in general sanitary conditions, the improvements required in tenement houses and the inspection and corrective measures of the Health Department. He declared, however, that the department did not have enough inspectors. He thought there should be a corps of at least forty medical inspectors, whose work should be exclusively devoted to tuberculosis. He also urged that it was an imposition to increase the cost of tenements by compelling increased measures against fire when fire did not cost more than forty lives a year. He believed it to be a serious error to restrict the height of tenements. "The problem before which all else gives way," he said, "is to furnish cheap homes, that shall have light, air and ventilation. The chance of death by fire is infinitely less than by disease. If the proper measures are taken I have no doubt that the disease can promptly be stamped out." Dr. Biggs also urged that all walls in tenement houses be painted instead of papered, and that no carpets be allowed in the halls. When asked if he meant this to apply to apartment houses he said that it would be better if it did.

Manager Fränkel of the United Hebrew Charities Association said that 3 per cent. of the applicants for aid to his Society had tuberculosis, contracted after their arrival in the United States. He thought it came from overcrowding, because the same percentage exists in Philadelphia where there were no tenements. There, he said, the poor Jews herded in three-story houses just as they do here in the tenements.

Dr. Anna Daniel of the New York Infirmary for Women and Children was of the opinion that the manufacture of clothing in tenements was a grave source of reflection. She knew many victims who worked on clothing up to the day before they died. The garments were often used for bedding, and they went out thoroughly infected with the bacilli of tuberculosis. She was opposed to high tenements, as were also Dr. Alfred Meyer and Dr. S. A. Knopf. They thought high tenements made the lower stories damp and dark and unfit for human beings to live in. None of those testifying believed that tenements should be permitted on 25-foot lots.

Craig Colony.—A pathologist with a salary of $2500 per year has just been allowed the Craig Colony for Epileptics at Sonyea, N. Y.

Dr. Markoe Celebrates His Golden Wedding.—On November 20, 1900, Dr. T. M. Markoe, Emeritus Professor of Surgery at the College of Physicians and Surgeons (Columbia), received a number of friends in honor of the fiftieth anniversary of his marriage. There was also present a committee from a musical club that has met uninterruptedly at Dr. Markoe's home for more than half a century. Both of Dr. Markoe's sons are, like their father, prominent members of the medical profession of New York City.

University and Bellevue Hospital Medical College Bulletin.—At the November meeting of the New York University Medical Society, a report of the Committee on a Bulletin appointed at the October meeting was accepted and referred to the Faculty for approval. This report planned for the establishment of a Bulletin to be issued four times annually, to be called *The New York University Bulletin of the Medical Sciences* and to be edited by a Committee of the Society under the business management to be designated by the university. The contents of the Bulletin are to be: (1) Original articles directly contributed to the Bulletin. (2) Abstracts or *extenso* reproductions of articles originally published elsewhere. (3) Short communications made at the meetings of the Medical Society. (4) Brief minutes of those meetings. (5) Reports on methods devised or tested in the departments of the medical college. (6) A reference list of publications by those connected with the medical college.

PHILADELPHIA.

Sun Porches at St. Joseph's Hospital.—New sun porches at this hospital have just been completed.

They are in the rear of the hospital and are 200 feet in length. Arrangements for heating make them available during the winter.

Experiments in Sewer Gas Destruction.—A station has been erected at Roxborough for the purpose of making experimental tests in the destruction of sewer gas. The results of the tests thus far are reported to be satisfactory.

Reception to Dr. Osler.—The Faculty Club of the University of Pennsylvania entertained Dr. William Osler of Baltimore at dinner Thursday evening, November 15th. The dinner was followed by an informal reception at the clubhouse.

Philadelphia Hospital Ambulances at the Disposal of the Police.—By order of Dr. Shoemaker the ambulances of the almshouse will in the future be sent for cases heretofore taken by patrol wagons. This, it is stated in the order, will not only save the making of long trips by the patrol wagons, but is also a more humane and proper way of conveying people to the hospital.

Increase in Death-Rate.—The low mortality of the past week has been ended by an increase of 70 in the number of deaths for the week ending November 17th. Diphtheria is not abating, 160 cases and 21 deaths being reported. In Camden there were 119 cases, the greatest number in the history of that city. The spread of the disease there is charged to the non-reportal of cases which has thus prevented the necessary quarantining.

Dr. S. Weir Mitchell Honored by Fellow-Townsmen.—Dr. Mitchell was the guest of honor at a reception given at the Penn Club Saturday evening, November 17th. A feature of the reception was that the gathering of 500 persons was largely made up of non-medical men. There were present many distinguished representatives of the pulpit, the bench and bar, and the business community. When a young man Dr. Mitchell spoke to Oliver Wendell Holmes about his desire to take up writing as a profession. He was advised by the "Autocrat of the Breakfast Table" to stick to medicine, make a success of that and then later in life return to the field of letters. Dr. Mitchell accepted with gracious modesty the congratulations which were bestowed upon him for achievements in the two professions which he had hesitated between years before.

University of Pennsylvania Alumni.—The Philadelphia Alumni Society of the Medical Department of the University of Pennsylvania held a symposium, Saturday, November 17th, at the Bourse. Dr. J. Madison Taylor, President of the Society, officiated as chairman, and the evening was delightfully spent with song and story. A banquet was served previous to the literary entertainment. The speakers all described the changes that had been introduced in teaching their several branches of medicine and surgery. Provost Charles C. Harrison was well received, as was also Dr. Egard F. Smith, Vice Provost. Dr. William Draper Lewis spoke for the department of law; Dean John Marshall, for the department of medicine; Dr. Essig, for the department of dentistry; Dean John W. Adams, for the department of veterinary medicine; Stewart Culin, for the department of archeology, and B. Franklin Stahl, Corresponding Secretary, who spoke for the General Alumni Society. Among the physicians present were Dr. De Forrest Willard, Dr. Roland G. Carter, Dr. Alexander C. Abbott, Dr. Mordecai Price, Dr. J. P. Crozer, all of Philadelphia; Dr. Henry Beates, President of the State Medical Examining Board; Dr. J. L. Forwood, of Chester; Dr. H. C. Whitcomb, of Norristown; Dr. Guy Hinsdale and Dr. Frank Elder of Philadelphia.

Typhoid in Pennsylvania.—Typhoid fever has become epidemic in Cementon, a town on the Lehigh River not far from Allentown. Of 200 families composing the population, there are one or more cases in 118 families. Of 22 families, all members from the father down to the youngest child are prostrated by the disease, which has now been raging two weeks. There have been several deaths during this time and the condition of many is reported to be critical. The cause of the epidemic is believed to rest with the town's water supply which has been taken from the Lehigh River. From the evidence already secured it would seem that the river is a stream of contagion distributing its poison over a wide area and seriously threatening other towns below Cementon which also get their water supply therefrom. The populous towns of Catasauqua, Bethlehem, Allentown and Easton are all on the Lehigh, and there is said to be typhoid in these towns also.

School Physicians Organize.—The visiting physicians of the schools of the city are at variance as regards the advisability of asking remuneration for their services. At the last of several meetings held for consideration of the subject a permanent organization was decided upon. Although there was much opposition, a committee was finally appointed to ask Councils for an appropriation to pay each physician a salary of $50 per month. The majority of the women physicians antagonized this action. It is feared by some of the 200 visiting physicians that efforts to secure salaries will lead to the abolition of the visiting staff. The late move of the Board of Education in this direction was stopped before application was made to the City Councils.

The Registration of Tuberculosis.—The meeting of the County Medical Society, November 14th, was devoted to a discussion of this subject. Dr. Hermann M. Biggs, of the New York Department of Health, was the guest of the Society and read the paper of the evening. Dr. Biggs discussed in an impartial manner the good and bad points of registration and gave the results of his twelve years' experience in the sanitary problems involved. Statistics have been quoted so often that the people, the Legislatures, the

sanitary authorities, and even the medical profession are becoming indifferent to the vast expenditure of money, suffering, and death. Dr. Biggs maintains that notification does not involve any publicity that did not previously exist. The increasing knowledge among the laity regarding tuberculosis will subject the consumptive to as great hardships as will notification. Measures differing essentially from those enforced in the acute contagious diseases should be adopted. Tuberculosis should be declared to be an infectious and communicable disease, and treated alone or in a class including typhoid fever and perhaps some other diseases. To properly deal with tuberculosis, sanitary supervision in every municipality should comprise: (1) Compulsory notification; (2) suitable plans for the education of the people; (3) a complete and efficient scheme for the disinfection or renovation of premises vacated by death or removal; (4) a hospital equipment; (5) the power of compulsory removal and retention of patients in a hospital when necessary, in the same manner as is practiced in the contagious diseases. Dr. Biggs closed his admirable address by stating that there had been a reduction of more than 35 per cent. in the mortality from the tuberculous diseases in New York City since 1886, and that it is his belief that a complete and efficient scheme can be adopted which will further reduce that mortality at least one-third within the next five years.

In the discussion of the subject City Bacteriologist Abbott stated that compulsory notification would engender no publicity, the purpose being to acquaint a central power with the location of the foci of disease in the city. Dr. Meigs opposes registration for two reasons: First, it is not successfully carried out, and, secondly, even if it were in every case, there would not be an adequate return for the work involved. He believes there is a difference in the results of precautions against the disease as claimed by laboratory workers and Boards of Health and the practical results seen by physicians. Dr. Flick, in the interests of the Free Hospital for Consumptives, has visited the homes of several hundred poor consumptives where communication of the disease is unavoidable because of the surroundings. Long continuance of the disease in these quarters makes it almost as virulent as smallpox. Dr. Ott stated that if compulsory notification were in force those physicians who adhere strictly to it would lose patients because of their known actions. This would cause evasion of the law and is an obstacle to be overcome.

The general sentiment of the Society was strongly in favor of registration, and a resolution was passed asking the Bureau of Health to class tuberculosis as a transmissible, notifiable disease and to take measures for its prevention.

CHICAGO.

Chicago Drainage Canal.—This great channel has not only purified the drinking-water supply of the city, but it has also given purer water than before to every city along the Illinois and Mississippi Rivers as far as St. Louis. The water in the canal, in the Desplaines River, and in two other rivers is purer from one end to the other to-day than it was a year ago before the canal was opened.

Chicago College for Nurses.—A college bearing this name has been founded, with the intention of training women in all duties of skilled nurses, without requiring two years of bondage in hospitals and training schools.

Board of Education.—In view of the excellent results of medical inspection of schools last year, Dr. W. S. Christopher, a member of the Board, wants the inspection of both public and parochial schools placed under the care of the Health Department.

Maurice Porter Children's Hospital.—This hospital, founded by Mrs. Julia F. Porter in 1882, began with eight beds and for twelve years was supported entirely by Mrs. Porter. Mrs. Porter later decided to extend the work beyond her individual charity and found a large free hospital for children suited to the needs of this great city. The hospital is absolutely free; there are no pay patients whatsoever. It undoubtedly will be greatly enlarged and its usefulness extended. The expenses of the hospital are met in part by an endowment of $3000 a year by Mrs. Porter, two endowed beds, and several annual contributions. The rest must be raised by private subscription and by an associate membership.

Augustana Hospital.—During the years 1884-1900 7051 patients were treated, representing 18 nationalities, 19 creeds, and 22 States. The total indebtedness is $49,436.90, incurred when the location was purchased, and when the new hospital building was erected. The institution has room for 125 patients, is supported partly by paying patients and partly by donations and collections from churches.

A Temperature of 127° F.—Robert Bruce, lately returned from service in the Ninth Infantry in the Philippines and China to Chicago, is reported to have this high temperature. Several days ago Bruce entered the City Hospital and asked for treatment. When the house physician took his temperature, and found it to be 112° F. and the patient showing no sign of early dissolution, he was astonished. The next day it was found that the clinical thermometer had not sufficient range. Other physicians were summoned and a Government thermometer applied, the mark of 127° F. was registered, and for several days in succession Bruce's temperature has reached this point. It is reported that Bruce's pulse does not go up in proportion to his temperature. An explanation given as to Bruce's condition is that a bullet which pierced his mouth lodged in the heat center of the brain.

Lupus Healed by Means of Roentgen Rays.—At a meeting of the Chicago Medical Society, held November 14th, Dr. W. A. Pusey demonstrated this case. The patient was a woman, thirty-eight years old, otherwise in fair health, without history of any sort of preceding eruption. Family history tuberculous. The diseased area involved the left cheek, the left side and front of the neck, the lips at the left angle of the mouth, and the chin, and extended up on the right cheek beyond the angle of the mouth. The disease was of four years' duration and had steadily progressed. At the time treatment was begun there was an active lupus area, with characteristic ulcers covered with reddish crusts and thick, band-like scars in which there were at many points recurrent ulcers and lupus nodules; characteristic tubercles were to be seen at many points. Tubercle bacilli were found in sections of tissue taken from the border of an ulcer. The patient was put under treatment with Röntgen rays on May 8th, and, with the exception of six weeks when there was no treatment, had almost daily exposures until November 14th. The only other local treatment was the use of boric-acid vaseline while the surface was freely ulcerating. Internally the patient took a pill of reduced iron, arsenous acid and strychnine, three times a day, during the month of October. Beginning May 8th the exposures were made daily until May 26th. After May 26th daily exposures were interrupted by intervals during which there was no treatment, the exposures always being temporarily stopped on the development of slight dermatitis. Within two weeks after the beginning of treatment the ulcers were cleaning up and improvement after that time was continuous. The last lesions had entirely disappeared by October 8th. An interesting observation was that lesions which did not receive the full effects of the rays required extra exposures for their healing. No new lesions have appeared and at the present time it is impossible to find active trace of the disease. The scars resulting are soft, flexible and white, confirming the claims of other observers. The thick lupus scars which existed when treatment began have shown under the exposures great improvement in flexibility, softness and color. The case was presented as one healed by exposures to Röntgen rays. It was admitted that whether it is a complete cure or not can only be determined by the lapse of time. It was pointed out that there were at least no evidences of disease remaining and that even should more or less recurrence of the lupus take place the result might still be called extraordinary.

GENERAL.

Riot in a Medical School.—There was a riot at the Omaha Medical College November 15th, in which a hundred students participated. Two students were seriously injured, one perhaps mortally, and a dozen others were more or less hurt.

Plague in Cape Colony.—The bubonic plague has broken out among the natives near King William's Town, twenty-eight miles northwest of East London, Cape Colony. Three deaths have already occurred.

President of Johns Hopkins Resigns.—Dr. Daniel C. Gilman has sent in his resignation as president of this university because of advancing years. Dr. Gilman is now nearly seventy years of age. His resignation it to take effect February 22, 1901.

Chinamen and the Plague.—Over 5000 Chinamen have just returned to San Francisco from the fisheries, canneries and other industries on the western coast. According to reports many of these Chinamen are greatly emaciated and weakened by hard work and poor feeding. There is fear that they will contract the bubonic plague when they get back to Chinatown.

Doctor and Automobile.—Dr. Francis H. Munroe, of Newark, N. J., was said last week to be recovering rapidly from injuries received in an automobile accident.

Rabbits and Diphtheria.—Newspaper reports say that the town of Grafton, Ill., is undergoing an epidemic of malignant diphtheria, which physicians believe was communicated to persons by rabbits. A great many rabbits have infested the country surrounding Grafton this fall, and the hunters put them on the market at prices so cheap that they were used largely as food. Within the last week hundreds of dead rabbits have been found near the town. It is said that the local practitioners became convinced that the rabbit flesh was responsible for the illness and caused microscopic examination, which proved that the rabbits found dead had succumbed to diphtheria.

St. Louis Academy of Medical and Surgical Sciences.—At the last meeting of this Society the following officers were elected for 1901: President, Dr. Emory Lanphear; Senior Vice-President, Dr. Carl Pesold; Junior Vice-President, Dr. H. S. P. Lare; Secretary, Dr. O. L. Suggett; Treasurer, Dr. G. M. Phillips; Orator, Dr. Wm. Porter; Librarian, Dr. H. G. Nicks.

Yellow Fever at Natchez.—The latest advices from Natchez report that at a conference of nearly all the physicians of the city November 9th it was stated that 12 cases of yellow fever with 7 deaths had occurred since about the middle of October. There were 5 known cases on the 9th, 2 new on the 8th. Local authorities say they will isolate and guard cases and suspects and make post-epidemic disinfection. Local conditions favor the control of the disease. The weather is cool, bright and clear.

A Physician Vindicated.—Adelbert Swartz, of Indiana, convicted of the murder of his brother-in-law and given a life sentence in the penitentiary at Jackson, Mich., in 1895, will be liberated within thirty days. Proof of his innocence has

come to light, and the Pardon Board has recommended his release.

Intemperance in Russia.—The Government is displaying great interest in the temperance movement. The Minister of Justice has transmitted to the commission appointed to reform the penal code a proposition emanating from the National Hygienic Society to forcibly detain confirmed inebriates in hospitals.

The Denver College of Medicine.—This institution, prominent among the smaller medical colleges, enters upon its twenty-first session with the best class of students in its history. Its laboratory facilities are greatly amplified and its clinical advantages materially improved. The department of pathology and histology has been placed under the care of Dr. J. A. Wilder, that of anatomy under the care of Dr. S. B. Childs.

Suicides and Homicides in the Army.—Surgeon-General Sternberg has prepared statistics making a comparison of cases of suicide and homicide which occurred in the Army during the years of 1898 and 1899 compared with the ten years between 1888 and 1897. Revising our report of the 17th inst., the statistics show that there were relatively fewer homicides during those two years than during the previous decade. The average number of suicides per year in an army of 27,116 for the ten years was 17, equal to a ratio of .63 per thousand. The strength of the Army in 1898 is given at 147,795, the number of suicides 38, and the ratio per thousand .26. The strength of the Army in 1899 is given at 105,546, the number of suicides at 30; ratio per thousand .28. During the ten years from 1888 to 1897 the mean annual number of homicides is given at 5.5, the ratio per thousand being .20. For 1898 the number of homicides was 19, and the ratio per thousand .13; for 1899 the number of homicides was 23, giving a ratio of .22 per thousand men.

Yellow Fever in Nicaragua.—*El Comercio* of Managua, Nicaragua, in its issue of October 18th, declares that yellow fever is prevailing in the city of Leon, near the Pacific port of Corinto, to an alarming extent, and that the disease is of a very dangerous type.

Yellow Fever and Santiago.—According to *The New York Times* this city has been rid of its yellow fever. It says: "The yellow-fever epidemic at Santiago in 1899 resulted in a death-rate of 20 per cent. of all who contracted the disease. This comparatively low rate was only obtained through the great moderation of the disease toward the end of the season, when the force of the storm had spent itself. Of the first seven men who were taken to the yellow-fever hospital but two recovered. General Wood was absent in the North when the epidemic began. It raged without abatement until his return, when he took prompt measures to quench the fires by removing the fuel on which they fed. Within a few hours every American soldier in the city was on his way to the mountains; department headquarters were removed to a safe village at a high altitude, and prompt isolation of suspicious cases and disinfection of houses they had occupied were made. All American bars were closed and other liquor-shops were forbidden to sell to Americans. All non-immune loiterers about saloons were isolated and disinfected as if they had been exposed to the disease. Hotels and lodging-houses in which cases had occurred were closed. Quarantine measures were strictly enforced, and non-immune passengers were not permitted to land in Santiago until late in the autumn. The disease soon began to wane. By the middle of October department headquarters were able to return to the city. The result of two years of American rule had been to make Santiago, to all outward appearances, as clean as any American city. A medical officer of the army, as Sanitary Inspector, has made a house-to-house inspection throughout the city. The Colonel has had the cooperation of the city authorities, who have made it a misdemeanor, punishable with fine and imprisonment, to resist this inspection or to fail to carry out the resulting orders. Where poverty prevents compliance with orders to clean up the work is done at the public expense, but, public or private, the work has to be done. Every house where yellow fever occurred last year has been disinfected three times. Eighty-five miles of streets in Santiago have been swept daily, and 25,000 cubic yards of sweepings have been hauled out of the city during the year. One hundred and eighteen thousand cubic yards of garbage have been removed, in the destruction of which 35,000 gallons of crude petroleum have been used. Four thousand gallons of carbolic acid and 11,000 pounds of chloride of lime have also been employed in the same work. A Board of Health, organized by Colonel Whitside, advises on all sanitary matters within the city and collects vital statistics. Any case of contagious or infectious disease reported is at once examined by three members of the Board, and no case is officially recognized except when the diagnosis is agreed on by a majority of the Board. A strict quarantine is maintained against towns where yellow fever is known to exist, and from which people may reach Santiago within the detention period of five days. Detention camps are organized for the observation of suspicious cases. The result of this work is that there has been no fever in the city since last December. Had fever come in spite of all that was done, everything was organized to take care of it. Its banishment from this city, its favorite habitat for three or four hundred years, has been accomplished by American cleanliness and energy, intelligently directed by military authorities, and its absence has been neither freak nor accident."

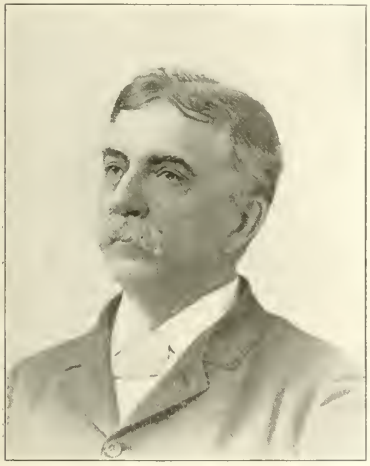
The excellent showing reflects great credit on the administration if further reports are corroborative.

OBITUARY.

HORACE TRACY HANKS, M.D., LL.D.

Dr. Horace Tracy Hanks died at his home, No. 766 Madison Avenue, of nephritis, Sunday, November 18th, after an illness of one week. He was born in Vermont in 1837. After two years at the University of Vermont and some winters' teaching in the public schools of East Randolph, Mass., he entered the Albany Medical College, from which he was graduated in 1861. He served in the Union Army as assistant surgeon with the Thirtieth New York Volunteers. In 1863 he resigned and went to Royalston, Mass., where he practised for a year, and then removed to New York in 1865.

Dr. Hanks was gynecologist at the De Milt



Horace Tracy Hanks, M.D., LL.D.

Dispensary from 1872 to 1882; assistant surgeon at the Woman's Hospital from 1875 to 1879, and surgeon since the latter year. Since 1885 he had been professor of diseases of women in the New York Post-Graduate Medical School and Hospital. He was also consulting gynecologist to the Northeastern and Judson Dispensaries and to the Tarrytown Hospital.

Dr. Hanks had a marked and high order of mechanical originality which was utilized in the construction of new instruments, many of which are now in use. He was also largely engaged in interests outside of his medical work and his social engagements were numerous. He was a member of the Republican and Quill Clubs, the Society of Medical Jurisprudence, the Sons of the Revolution, Lafayette Post of the G. A. R. and the New England Society.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, November 14, 1900.

SCANDAL AT THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC—APPOINTMENT OF A COMMISSION OF INQUIRY—LETTER OF SIR WILLIAM BROADBENT—PRECAUTIONS IN LONDON AGAINST THE PLAGUE—MR. JAMES CANTLIE'S DESCRIPTION OF THE DISEASE—THE RETURN OF THE CITY IMPERIAL VOLUNTEERS—MANY CASUALTIES IN WITNESSING THE PROCESSION.

The conflict between the board and staff of the National Hospital for the Paralyzed and Epileptic, of which I advised you some time ago, still continues. It may be remembered that the staff alleged that grave defects existed in the administration—an insufficient supply of nurses and improper dieting of the patients—and made the very modest request that they should be allotted two seats on the board, pointing out that such an arrangement would render impossible the existence of the evils mentioned. The board adopted an unreasonable and overbearing attitude and refused this request, giving as a reason that the conduct of one of their medical officers might at some time have to be called in question before the board and that he might, therefore, be placed in the anomalous position of sitting in judgment on himself. To this weak argument I have already replied. Finding protests useless, the staff has through the press brought the matter before the public and the board has at last been compelled to consent to an inquiry by an independent tribunal. In *The Times* a controversy has been carried on for several months in which many of the leading consultants of London have taken part. Sir William Broadbent treats the subject in a very trenchant manner. The public, he says, scarcely realizes the issues which are at stake. The demand that two representatives of the staff should have places on the board conveys a totally inadequate idea of the importance of the question involved. It is put forward as a means of redressing grievances which have become intolerable. The physicians and surgeons of a hospital have their minds too fully occupied with the care of the patients to desire to take part in the administration of the institution, so long as their instructions are carried out. In no department of medicine are the problems of disease more difficult and absorbing than in neurology and nowhere has better work been done in their elucidation than at the National Hospital. How grave must be the matter, then, which could provoke a unanimous protest from men engaged in such studies! The staff of the National Hospital occupies an exceptional position. Most hospital physicians and surgeons owe at least as much to their hospital in opportunities

and reputation as the hospital owes to them. But the National Hospital is the creation of the distinguished men who form its staff. No other institution can present such a galaxy of names absolutely in the front rank. Buzzard, Bastian, Gowers, Brundell Carter, Ferrier, Semon, Hughlings Jackson, to go no further, are known all over the world. These are the men who are brought to the verge of collective resignation by a board quite incompetent to give any opinion on their complaints!

As a precaution in case plague should invade the metropolis the London County Council has had written a pamphlet containing a concise description of the disease by Mr. James Cantlie, formerly medical officer in one of the plague hospitals in Hong-Kong and Dean of the Medical College of Hong-Kong. A copy of this pamphlet has been forwarded to all the practitioners in London to assist them in the diagnosis of the disease. The Council has also engaged the services of Mr. Cantlie to visit any person in London suspected of suffering from the disease. Any medical man can avail himself of these services by simply applying. As very few practitioners have ever seen a case of plague this arrangement must prove a great boon in cases of difficulty. But thus far only one doubtful case has occurred and this turned out not to be plague. Mr. Cantlie points out that in former times the word plague was applied to almost any epidemic, but in recent years it has come to designate a specific disease. He recognizes 8 types, *viz.*, (1) bubonic, (2) septicemic, (3) pneumonic, (4) nervous, (5) fulminant—in which the patient quickly collapses and dies within twenty-four hours, (6) puerperal—in which abortion occurs, (7) pestis ambulans in which the patient goes about and performs his ordinary duties, (8) pestis minor—a mild form which occurs not only when the epidemic is at its height, but for several months (or years) before and for several months (or years) after. The importance of the latter form is that it may precede an outbreak. The symptoms are swelling of an inguinal gland, fever and malaise. The bubo suppurates and discharges by two, three or more fistulous openings. After excision healing takes place in a month and the patient is cured. Plague is spread chiefly by human agency, but rats, body and household parasites, food, drink, and air are all means. The excreta—feces and urine—contain the bacillus. The sputum is the most infectious of all. It is by the vermin in the coat of rats which leave it after death that infection is probably conveyed to man.

The return of the City Imperial Volunteers from the war was witnessed by a throng of people in London, the extent of which has never been exceeded, and was attended by over 1000 casualties of which two were fatal. In several places the police charged with keeping the route clear were overwhelmed by the vast multitude, and quite powerless. At one hospital, St. Bartholomew's, 70 cases were treated of which 13 were retained. They included abdominal and head injuries and cases of fractured ribs. Two men standing on a scaffold fell to the ground and were killed. The scaffold gave way owing to the attempt of a number of persons to climb it.

British.

ETIOLOGY OF RHEUMATIC FEVER—PHTHISIS AND WIND—ARTHRITIS AND APPENDICITIS—EARLY OPERATION IN APPENDICITIS—ACUTE PULMONARY VALVULITIS—ACUTE ACTINOMYCOSIS—MEDICAL CARE OF GYNECOLOGICAL CASES.

F. J. Poynton and A. Payne at the Pathological Society of London, October 16th, read a paper on the etiology of rheumatic fever which was an epitome of their report *in extenso* of observations and experiments read in June and made up to that time and an additional memorandum of such as have been had since that time. The paper consisted of three parts: (1) The results obtained in the original eight cases with those in the subsequent three new cases of the fever by injecting the diplococcus recovered from all eleven into rabbits. (2) A comparison was made between the lesions in the human being and in the rabbit. (3) An exhibition was given of the microscope slides and a few macroscopic preparations of the lesions caused by this displococcus. The authors laid stress upon the fact that all the cases of rheumatic fever had been very typical and none doubtful The diplococcus had been grown in pure culture in a medium composed of milk and bouillon acidified by lactic acid and then transferred to blood agar. Injected intravenously into rabbits it caused death rapidly by acute valvulitis. The diplococcus was then isolated from the blood and cerebrospinal fluid and cultivated as before. Injected into a young rabbit it caused endocarditis and polyarthritis with much effusion. Local and systemic recovery ultimately followed. This same organism had been found in the bladder after death and in the urine during the course of acute pericarditis. Such injected into rabbits caused pericarditis, endocarditis, polyarthritis, emaciation, pyrexia and death on the twentieth day. There was no suppuration in any of the viscera. Chorea was noted once combined with great nervousness of the animal and at autopsy valvulitis. Their microscopic examinations were not yet completed, but one remarkable fact was recited, *viz.*, when the lesions, especially the pericarditis with effusion, were not marked, a large coccus was recovered with relatively few of the diplococci. The same atypical coccus could be produced by cultivating the diplococcus upon improper media and seemed to indicate changed virulence or chemistry of the organism or both. They appeared as evidence of the subsidence of the lesion. In some cases of malignant endocarditis the converse was found,

namely, very numerous active diplococci. Perhaps relapses in rheumatism might be explained by some latent energy in the large cocci. In conclusion they expressed the theory that in rheumatism there is great local resistance whence is found the evanescent character of the lesions, pericarditis, endocarditis, etc. They have noted large numbers of the diplococci taken up in the bodies of the connective and endothelial tissue cells.

W. Gordon (Exeter) at the Royal Medical and Chirurgical Society recited investigations into the influence of wind upon phthisis in the county of Devonshire and the bearing such would have upon choice of sites for sanatoria for consumptives throughout Great Britain. His plan was first to compute the ratio for each district of the death-rate due to pulmonary tuberculosis to the total number of deaths, on the ground that the latter is usually an index of the general sanitation of a community. Then he proceeded to assign causes for the phthisis where there was an undue number of cases of it. Rainfall appeared to have some influence, for in Tavistock the rain and the disease were both at the maximum, while at Axminster each was at the minimum. Other considerations indicated a common cause for this relation, possibly the wind which brought the rain. It seemed scarcely possible that the geologic conditions of the soil could be a factor. The theory of wind influence upon tuberculosis is not new, but he tested it thoroughly in this shire. He found the lowest mortality in communities where the houses were well sheltered, the greatest mortality where they were much exposed, especially to the west and southwest winds. He did not think that temperature, sunshine and purity of air could have much influence, but regretted that they could not well be reduced to definite computation.

F. J. Poynton at the Medical Society of London, October 22d, discussed the relation between appendicitis and arthritis. The concurrence of these two diseases is not common, but deserves elucidation in order to explain the causes of the appendicitis. Many claim that these may be rheumatic in origin, because of (1) the concurrence of appendicitis and acute articular rheumatism; (2) the occurrence of a polyarthritis resembling an acute rheumatism either during or just after an appendicitis; (3) the favorable reaction in appendicitis to salicylates; (4) the analogy of structure between the tonsil and the appendix. His own view is that this association is not conclusively causal, although both may be cured by the salicylates. It is further very likely that the arthritis in appendicitis may be purely pyemic by metastasis, as is often shown on autopsy. A purulent or gangrenous appendix will have metastases elsewhere pyemic in character, it may be in the lungs, liver, other viscera or joints. Finally, it should be remembered that monarticular lesions in children, like hip affections, even if rheumatic, may on the right side simulate appendicitis and that in pronounced rheumatic attacks in children the abdomen is often the seat of distress.

C. W. M. Moullin at the Harveian Society of London, October 18th, read a paper on the early operation in appendicitis. All attacks of this disease he considers are divisible into three groups: First, those which have a mild invasion, short course, need no operation and always yield to medicinal and dietetic management. They make up by far the greatest number of patients. Second, those who are afflicted by a severe attack; in them the appendix is severely infected, goes on to suppuration and adhesions, abscess or gangrene results. These patients are less numerous than the preceding class, should always be operated on and usually are, but entirely too frequently the treatment is too late. The third series of a case is the peritonitic, where the appendix ruptures prematurely and freely in the general peritoneal cavity. Such patients are often lost notwithstanding early and drastic operation. In dealing with any case of this disease several axioms must be remembered. These are the frequently virulent and rapid invasion and course of the process, the anatomical freedom of the appendix to swing to almost any point of the abdominal cavity and, rupturing, dump its septic contents and set up a furious peritonitis; the deceptive latent possibilities of a case which has had a very mild initiation, but without warning may be modified to an intense course and fatal issue, and, finally, the common experience that an original insignificant attack may be followed by one of early fatality either in itself or in the patient's surroundings which may be far from the reach of skilled surgical aid. In view of these facts the real danger for the patient lies not in the comparatively safe operation of removing the organ while slightly diseased and not adherent, but certainly in delaying to do so. The only symptoms which will serve as guides to the moment of operation are the pulse, temperature, tenderness, muscular rigidity and pain and sense of fulness in the right iliac fossa. With the patient in bed a constant pulse of over 100 or a rise to that level and over is the best single sign. The temperature is by itself less reliable, unless there be a steady rise or a sudden rise. Increase in the pain, tenderness and muscular rigidity is very significant. A sense of fulness or tumor in the right iliac region is pathognomonic. Vomiting and constipation and other symptoms are much less reliable as guides. The absence of any special sign is not solely a reason for waiting. The presence of a rapid pulse, even if other conditions appear quiescent, is full reason for immediate operation. This is still more emphatic if morphine has been administered. The limit of waiting may be arbitrarily put at thirty-six hours, but each case must be decided on its own merits. In some this will be too long: in other cases delay may be properly prolonged. The danger lies in making the error and postponing the operation

till too late. The difficulty lies in distinguishing a severe case at the outset. It is at this period that the operation possesses very little danger and should be known as a truly preventive measure. In view of all the difficulties possible in any case he thinks this immediate preventive operation always justifiable; first, because it has little hazard itself, second, because it is safest to ablate any diseased appendix

T. Churton at the Pathological Society of London, October 16th, showed a specimen of acute pulmonary valvulitis. The child, eleven years old, was perfectly well until she had her first attack of rheumatic fever in her fifth year; in her eighth year she developed pulmonary tuberculosis with hemoptyses and the following year had acute rheumatism with pneumonia. During her last illness a loud rushing bruit was heard in the second left intercostal space and the diagnosis of pulmonary stenosis was made. The autopsy showed vegetations along the valves and marked narrowing. The foramen ovale, ductus arteriosus and septum ventricule were all closed.

D. Duckworth at the Clinical Society of London, October 12th, rehearsed the history of a case of acute actinomycosis in a nineteen-year-old youth. He was admitted September 28, 1899, complaining of pain and swelling in left chest low down. He had had gastric pain after eating for months before admission, but this had passed off. When he came to the hospital he had a temperature of 99° F. and pulse of 100, deficient respiration in the left lower chest with gradually increasing bulging, dulness and absence of breath sounds in the axillary region below the sixth rib, dulness and friction crepitus for four inches behind. The bulging was partly thoracic and partly abdominal and seemed to involve the left lobe of the liver, which was exceedingly tender and displaced by respiration. October 25th the temperature reached 102° F. and 102.8° F. on the 26th. Abscess of the liver was vainly explored for and actinomycosis suggested, but could not be established. At the autopsy actinomycosis of the left lobe of the liver, a softened mass between it and the pylorus and a subdiaphragmatic and left pulmonary abscess filled with ray fungus were found. The source of infection may have been the old gastric ulcer.

H. Smith at the British Gynecological Society, October 11th, deprecated the fact that modern surgical successes had made the operative treatment in gynecology overshadow the medical treatment. There are many conditions in which locally and systemically medicines, diet and hygiene may cure and the dangers of operation be avoided.

Hospital Site Purchased.—The Sisters of the Poor of St. Francis, who conduct the St. Francis Hospital, have bought the plot of thirty-two lots on the east side of Brook Avenue, from 142d to 143d Street. The property will be improved with a hospital building.

SOCIETY PROCEEDINGS.

CHICAGO PATHOLOGICAL SOCIETY.

Stated Meeting, Held October 8, 1900.

The President, Ludvig Hektoen, M.D., in the Chair.

Milk Supply.—Dr. S. E. Munson of Springfield, Ill., read this paper, in which he discussed in particular the relation between milk supply and tuberculosis. The recent literature bearing upon the subject was referred to and the use of tuberculin and the slaughter of cows giving a reaction were advocated.

Dr. W. A. Evans spoke of the various measures advocated for the elimination of tuberculosis from herds of cows, and concluded by advising the killing of all tuberculous cows, as has been urged by Virchow.

Dr. Gehrmann referred to the measures taken by the Chicago Health Department relative to the detection of tubercle bacilli in milk. The examination of a general milk supply for the bacilli has been discontinued, and only the milk from individual cows is tested. The use of tuberculin is always recommended in any case where suspicion is aroused, in preference to the examination of the milk. The detection of pus in milk is considered sufficient evidence upon which to condemn it, even in the absence of tubercle bacilli.

Neuro-Epithelioma.—Dr. Brown Pusey demonstrated specimens of a glioma of the retina. He said the fact that current pathological literature contains several articles on the subject of glioma of the retina has suggested the idea that the members of the Society might be interested in seeing sections from such a tumor. The present agitation on the subject of glioma of the retina undoubtedly is due to the article of Flexner, published August, 1891, and to the book of Wintersteiner, "Das Neuro-Epithelioma der Netzhaut," published in 1897. In these publications particular attention is paid to the "rosettes" found in such tumors. Wintersteiner described the rosette as composed of cells derived from the neuro-epithelial layer of the retina; the wall of the central cavity of the rosette, he thought, corresponded to the external limiting membrane of the retina, with rudimentary rods and cones projecting into the central cavity. Flexner and Wintersteiner, working independently, came to similar conclusions, and from these studies suggested the name *neuro-epithelioma retinae* to replace the term *glioma retinae*. These conclusions have been accepted by many authorities; others have opposed them. Two facts have been particularly hard to explain when considering these tumors as new growths derived from the neuro-epithelial layer of the retina. One is that, according to present views, such highly differentiated tissues do not form tumors; the other is

that the gliomata arising elsewhere than in the eye have very similar rosettes.

The tumor from which the specimens were taken was evidently removed in a very early period of its development. It shows the rosettes unusually well. Especial interest attaches itself to the specimen from the fact that there can be no doubt that the cells of the rosettes of this tumor do in places split up into fibrous tissue—into neuroglia. He thought it would require a great stretch of the imagination to look at some of the sections and then speak of rudimentary rods and cones projecting into the central cavity of the rosette. He believes that the specimens demonstrate that the rosettes are composed of cells which form neuroglia; in other words, that the suppositions of Flexner and Wintersteiner that these tumors are neuro-epitheliomata are incorrect, and that these tumors are, as was formerly believed, true gliomata.

In the discussion Dr. M. Herzog agreed that the tumor consisted of glia cells, and that if blood could be demonstrated in some of the spaces, the picture would correspond to a glioma of the central nervous system.

Castration Tumors.—Dr. H. Duncan demonstrated specimens of these tumors taken from swine, and said that there is a disease of swine characterized by a tumor or growth which, as a rule, appears after castration, occupying the position of the testicle. Similar growths occur, however, in other situations and usually on the breast in the female. A trauma of some kind invariably occurs previous to the appearance of the growth. The clinical history of the disease is briefly as follows: About two weeks after castration a swelling appears at the site of the castration wound. The tumor, as a rule, grows rapidly and in from three to five weeks one or more ulcers appear in the cicatrix. Close inspection shows the ulcers to be the external openings of fistulous tracts from which there is a constant discharge of purulent material—the discharge may be intermittent. Not infrequently the growth acquires enormous proportions as compared with the weight of the animal and in such cases may drag upon the ground. During the early stages the animal thrives, later it becomes cachectic, loses flesh and dies about twelve months after the inception of the growth. The growth is in anatomical connection with the distal end of the spermatic cord. It is in most cases single, but there may be two or more growths on the same side of the scrotum. It consists of a softened center enclosed by a capsule of firm, avascular, white, fibrous tissue. The fibrous tissue merges externally into a loose fibromyxomatous, sometimes edematous, tissue. The form of the swelling is generally round or oval. There may be smaller secondary tumors or nodules in close relation to the primary growth varying in size from that of a pea to that of a hen's egg, having a structure similar to that of the primary growth. More rarely small nodules are strong along th course of the cord. The histology of the growth is uniform and corresponds to the macroscopic appearance, *viz.*, a structureless, neurotic center with an enclosing zone of scar tissue. In sections stained for bacteria the neurotic border is seen to contain numerous organisms, sometimes in enormous numbers. There may be bacilli of varying lengths, threads and cocci. The threads stain uniformly or appear as strings of deeply-staining spores or cocci. Some of the threads branch. In all more than twenty tumors have been examined and cultures under both ordinary and anaerobic conditions have been made. Usually from two to seven different organisms have been isolated from each tumor examined. None of the organisms isolated were virulent enough to kill guinea-pigs. The bacteriologic results were not uniform. A ray fungus was isolated from three of a series of seven tumors. Smears from all of the series show threads, some of which branch. Swine were inoculated subcutaneously with pure cultures of the ray fungus with negative results. A sixty-pound male pig was inoculated by removing the right testicle, inserting a small piece of necrotic material from one of the growths and sewing up the wound. The result was a fairly typical growth at the site of the inoculation. It is interesting to note that the remaining testicle was partly neurotic, partly scar tissue, and a portion external to the growth was comparatively normal. The disease is not infrequent among the swineherds of the Southwest, as Iowa, Kansas, Missouri.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION

Thirteenth Annual Meeting, Held at Atlanta, Ga., November 13, 14 and 15, 1900.

The Association met in the ballroom of the Kimball Hotel under the presidency of Dr. A. M. Cartledge of Louisville, Kentucky.

Governor Candler of Georgia delivered an eloquent address of welcome, which was responded to by President Cartledge.

Medullary Narcosis.—Dr. W. L. Rodman of Philadelphia in reading this paper asked: Will the method displace ether and chloroform in operations below the diaphragm? No one, he said, however optimistic he may be concerning this new method will think of abandoning ether and chloroform. These trusted agents will continue to enjoy the confidence of the profession, and the Corning-Bier method will be held in reserve for certain cases in which there is seemingly a clear contraindication to chloroform or ether. Medullary narcosis should be given subjects suffering from bronchial, pulmonary, and renal diseases; to patients affected with fatty or dilated heart and cardiac diseases in general. It may also be given to old people in whom the shock of general anesthesia is oftentimes great, and, from its action in one case, the author believes it to be safer

than chloroform or ether in drunkards. The place where the spinal canal is entered is of some importance. Tuffier, Murphy, Matas, and others prefer the fourth lumbar space. In the opinion of the author any of the lumbar spaces can be punctured with safety. The fifth interspace between the last lumbar and the first sacral vertebra is in some respects the easiest route. The author considered the primary dangers of simple puncture without injection. It has not been shown that secondary changes, either inflammatory or degenerative, have taken place in membranes or cord leading to chronic disease. Theoretically, one might fear some form of sclerosis. Simple puncture of the spinal cord, if aseptically done, is unlikely to be followed by serious changes in the cord or its membranes. If to simple puncture is added the injection of some chemical substance by which anesthesia is produced, a new element of danger is undoubtedly incurred. Therefore, the choice of a local anesthetic becomes of paramount importance. Cocaine is difficult to sterilize, as it cannot be boiled without impairing its anesthetic properties. Raised to a temperature above 180° F., it is decomposed into ecgonin and becomes comparatively inert. Some have found it practical to boil cocaine and then introduce it into the spinal canal without impairing its anesthetic properties. By raising it to a temperature of 180° F., and repeating this twice, thrice, even six times, as recommended by Tuffier, it should be sterile, and therefore safe, and yet a dose of thirty minims of a two-per-cent. solution of cocaine is too large. Rodman recommended half of this amount. A small dose of a two-per-cent. solution is better than a larger one in greater dilution. He has reduced the number of minims of a two-per-cent. solution each time he has practised the method, and thus far he has not failed to obtain complete analgesia. In his first case he injected 18 minims; in the second, 15 minims, and in a third, 13 minims, and hopes still further to reduce the amount to 10 minims. One should aim to get complete anesthesia with the smallest amount of the drug. The primary and secondary effects of the injection of cocaine into the spinal canal are those of simple puncture exaggerated. Shock is increased, headache, restlessness, delirium, and other symptoms are necessarily more pronounced. The speaker referred to the method of injection. An iridoplatinum needle was recommended. Blindfolding the patient and filling the ears with cotton to avoid psychic pain are desirable.

Dr. Lewis S. McMurtry of Louisville predicted that medullary narcosis would not take the place of the established methods of anesthesia and that its field of usefulness would be restricted to the class of cases just outlined.

Dr. Willis G. MacDonald of Albany mentioned the case of a man, forty-two years of age, who had suffered from hemorrhoids and fissure of the rectum. The patient had always been a hard drinker. Granular and hyaline casts were found in the urine, also a small amount of albumin. Patient likewise had a fatty, dilated heart. He injected 18 minims of a two-per-cent. solution of cocaine in the subdural space, and when he was about to begin the operation the patient became cyanotic; a profuse, cold perspiration began, so that it became necessary to give the patient one-twentieth of a grain of strychnine, one-twenty-fifth of a grain of nitroglycerin, when the respirations ran up to sixty or eighty. No pulse was discernible at the wrist. The pupils were dilated; patient became unconscious. More than two hours elapsed before the speaker felt safe as to the condition of his patient. The man suffered severely from headache and projectile vomiting during the entire afternoon, and had two or three involuntary movements. Two days later Dr. Macdonald administered nitrous oxide and ether and operated on the hemorrhoids. Patient recovered. During the summer, while on a visit to Europe, he saw a similar experience in the practice of Professor Kocher.

Dr. A. M. Cartledge of Louisville said his experience was limited to eight cases in which he had used this method of anesthesia, the results being satisfactory. In two patients severe headache, which soon disappeared, followed its use. Analgesia was complete in all cases. In one case he operated for the removal of pus tubes; in a second he removed an enormous fibroid tumor of the uterus; and in a third a large intraligamentous cyst. Some of the patients came off the table in much better condition than if chloroform or ether had been employed.

Dr. E. P. Mallett of New York detailed a case of retroverted adherent uterus in the practice of Dr. Grandin in which an abdominal section was made. At first much difficulty was experienced in finding the subdural space or medullary canal, and the patient complained of intense pain. It was finally found, cerebrospinal fluid escaped, and cocaine was injected, the analgesia being apparently complete in eighteen minutes. So much pain was experienced while the operator was making the incision that it became necessary to administer a few whiffs of chloroform to complete the operation. He also detailed another case in which posterior vaginal section was done for pelvic abscess. In this case the needle was introduced more quickly and with better success; but slight vomiting, as well as other symptoms, occurred. The subsequent course of both cases was uneventful.

Dr. Beverly MacMonagle of San Francisco spoke of two cases which he saw in the practice of Dr. Barbat of San Francisco in which medullary narcosis was used successfully. However, he was told by both patients afterward, and by Dr. Barbat, that they suffered a good deal from vomiting after they had been taken to their rooms, but subsequently recovered without any marked incidents.

Dr. Seneca D. Powell of New York does not

think the time is ripe for this method to be presented to the profession at large. He cited two cases that had occurred in his own practice in which he had used cocaine saying that both patients came very near dying from its effects.

Dr. Rodman, in closing the discussion, said he had used medullary narcosis on a man, forty-five years of age, who had a bursa in the popliteal space, with marked kidney trouble. The result was satisfactory in every respect. The next case was one of advanced kidney trouble in which he did a suprapubic cystotomy. Result, satisfactory. He would use medullary narcosis in those cases in which there are positive contraindications to ether or chloroform. The surgeon should always obtain the consent of the patient before using the method on account of any medico-legal complications that might subsequently arise.

Removal of Pelvic Inflammatory Masses by the Abdomen After Bisection of the Uterus.—A paper on this subject was read by Dr. Howard A. Kelly of Baltimore. Recently the author pointed out the great advantages which accrue from bisection of the myomatous uterus in abdominal enucleation in certain complicated cases. In previous contributions he had described his method of enucleation by a continuous transverse incision from left to right, or from right to left. He now calls attention to the great value of a somewhat similar procedure in certain cases of pelvic inflammatory diseases. The steps of the operation are these: If the uterus is buried out of view, the bladder is first separated from the rectum and the fundus found. Then, if there are any large abscesses, adherent cysts, or hematomata, they are evacuated by aspiration or by puncture. The rest of the abdominal cavity is then well packed off from the pelvis. The right and left cornua uteri are each seized by a pair of stout museau forceps and lifted up; the uterus is now incised in the median line in an anteroposterior direction and, as the uterus is bisected, its cornua are pulled up and drawn apart. With a third pair of forceps the uterus is grasped on one side of its cut surface as far down in the angle as possible, including both anterior and posterior walls. The museau forceps of the same side are then released and used for grasping the corresponding point on the opposite cut surface, after which the remaining museau forceps are removed. In this way two forceps are in constant use at the lowest point. He commonly applies them three or four times in all. As the uterus is pulled up the halves become everted and it is bisected further down into the cervix. If the operator prefers to do a panhysterectomy, the bisection is carried all the way down into the vagina. The uterine canal must be followed in the bisection, if necessary, using a grooved director to keep it in view. The museau forceps are now made to grasp the uterus well down in the cervical portion, if it is to be a supravaginal amputation, and the cervix is bisected on one side. As soon as it is divided and the uterine and vaginal ends begin to pull apart, the under surface of the uterine end is caught with a pair of forceps and pulled up, and the uterine vessels which can now be plainly seen are clamped or tied. As the uterus is pulled still further up, the round ligament is exposed and clamped, then finally a clamp is applied between the cornu of the bisected uterus and the tubo-ovarian mass, and one-half of the uterus is removed. The opposite half of the uterus is also taken away in the same manner. The pelvis now contains nothing but rectum and bladder, with right and left tubo-ovarian masses plastered to the sides of the pelvis and the broad ligaments, affording abundant room for investigation of their attachments, as well as for deliberate and skilful dissection. The wide exposure of the cellular area over the inferior median and anterior surfaces of the masses, offers the best possible avenue for beginning their detachment and enucleation. The operator will sometimes find on completing the bisection of the uterus that he can just as well take out each tube and ovary together with its corresponding half of the uterus, reserving for the still more difficult cases, or for a most difficult side, the separate enucleation of the tube and ovary after removal of the uterus. The operation just described is not recommended to a beginner in surgery. The surgeon who undertakes it must be calm, deliberate, and must bear in mind at each step the anatomical relations of the structures. The author has had abundant opportunity to demonstrate the practical value of this method of treatment in his clinic this year. The advantages of a bisection and enucleation of the uterus as a preliminary to a complete enucleation of tubes and ovaries for pelvic inflammatory and other diseases by the abdominal route were briefly recapitulated as follows: (1) Additional space for handling adherent adnexa, afforded by the removal of the uterus. (2) Great increase in facility for dealing with intestinal complications. (3) Better access by new avenues from below and in front to adherent lateral structures. (4) Elevation of structures to or above pelvic brim, or even out into the abdomen, bringing them within easy reach of manipulation and dissection. (5) Some advantage in approaching both uterine vessels by cutting from cervix out toward the broad ligament as is secured in approaching one of them in the continuous transverse incision. In general the time of the operation is shortened; its steps are conducted with greater precision and surrounding structures are far less liable to be injured. In this way there are fewer troubles and sequelæ, and the mortality is lessened.

Dr. Willis G. Macdonald said his experience in bisection of the uterus had been very largely associated with tumors of the uterus deeply situated in the pelvis, attended with great tension upon both broad ligaments. In dealing with fibroids of the uterus it has been his custom to

follow the method improved by Dr. Kelly, and the only objection to the operation lies in a certain class of cases in which the tumor is deeply situated in the lower segment of the uterus, or extends to one side or the other in the broad ligament, or is associated with microcystic and adherent ovaries, so that, when the operator lifts the tumor out of the abdomen to begin preliminary ligation on one side or the other, he causes considerable tension upon the broad ligament, and when the ligature is placed upon one or the other ovarian artery there is more or less danger of it giving way when the tension is released. He has seen many cases in his own practice and that of other surgeons in which this accident had occurred.

Dr. J. Wesley Bovée of Washington, D. C., said he had occasionally removed the body of the uterus previous to the removal of the appendages in pus cases, also in fibroid tumors of the uterus. In some instances he had followed the method of Kelly. He had recently modified this plan in dealing with pus cases, *i. e.*, he has cut off the tube and ovarian ligaments from the uterus on one side, clamped the round ligament, going down to the cervix, clamping the uterine artery, cutting through the cervix and uterine artery on the other side, going up and removing the appendage on the other side with the uterus.

Dr. W. E. B. Davis of Birmingham, Alabama, expressed the opinion that the method outlined by Kelly would be of great assistance in the severe cases of inflammatory pelvic disease. The removal of the uterus for inflammatory disease had its origin in the difficulties which beset French surgeons in removing the appendages by the vaginal method, so that it became necessary for them to remove the uterus in order to have a route by which they could reach the adnexa. Dr. Kelly, therefore, has accomplished by operating from above what French surgeons had so frequently done through the vagina.

Dr. George J. Engelmann of Boston considers the method a step in advance and said it is really amazing that no one had thought of doing this work by the abdomen before it had been done by the vaginal route.

Vesico-Vaginal Fistula.—Dr. M. C. McGannon of Nashville, Tennessee, read this paper, in which he referred to the work of Sims, Emmet, Mackenrodt, and others, in this field of surgery. He has applied the principle of Mackenrodt in six cases, during the last two years, with primary union and complete closure of the fistula in every case. The technic in each case was the same, and this the author outlined at considerable length.

Osteofibroma of the Uterus.—Dr. George Ben Johnston of Richmond, Virginia, reported this case. The patient, Mrs. S., aged thirty years, is the mother of three children, the youngest being three years old. About two years after the birth of the youngest child she noticed an enlargement of the abdomen, and at times experienced difficulty in voiding her urine. She believed herself pregnant, but on account of the continuance of her menses and increasing difficulty of micturition, she consulted her physician and an examination of the genital organs was made. This examination disclosed a tumor which filled the pelvic cavity, growing from the posterior wall of the uterus and so displacing the uterus forward that it pressed upon the bladder. Six months later she missed her menstrual period, and by this time her size had greatly increased and her ability to void urine normally was almost lost. About the middle of March, 1900, after being all day upon her feet, a severe hemorrhage occurred and the next day she passed a fetus of six or eight weeks' development. Hemorrhage was promptly checked, but her size did not reduce and the pressure symptoms continued. He operated upon her April 10, 1900. Complete hysterectomy was performed. Macroscopic examination showed a tumor about the size of a small orange and of firm consistence. Held between the thumb and fingers, it gave the sensation that is produced by pressing a hard-boiled egg, the shell of which has been broken. Plates, apparently of bone, surrounded the surface, and on opening it a substance resembling medullary tissue was found. This was unfortunately lost, therefore no subsequent histological study of it could be made. Attached to the lower part of the osseous tumor was a small fleshy mass, which contained a body about an inch in length and resembling a heart in shape. On opening the uterus a recent placental site was found near the uterine opening of the right Fallopian tube. Microscopic examination of the tumor verified the diagnosis made macroscopically—osteofibroma. Patient recovered.

Dr. Howard A. Kelly said he would be loath to accept diagnoses that had been made twenty-five years ago in regard to tumors of this kind, when the difference between calcified tumors and teratomata was not clearly understood, and even pathology itself was in a vague condition. In 561 myomectomies he has met with 27 calcified myomata.

Dr. J. Wesley Bovée mentioned three cases that had come under his observation. In one the tumor was removed through the vagina, it being a submucous fibroid. The tumor passed down through the cervix, so that it required only slight slitting of the cervix to remove it. Around the base of it he found considerable bony structure in the body of the uterus near the fundus. Two other interesting cases were detailed.

Appendicitis in the Female.—Dr. F. W. McRae of Atlanta, Georgia, read this paper. At the outset the author referred to an exhaustive article by Edebohls as to the relative frequency of appendicitis in the two sexes; also to the work of Einhorn, who in 18,000 successive autopsies found perforating appendicitis in 55 per cent. of males and 57 per cent. of females. Robinson, in 128 autopsies, found evidences of past perito-

nitis in or about the appendix in 68 per cent. of females and 56 per cent. of males. Clinically, Edebohls finds that 4 per cent. of all women have appendicitis. On the contrary, Deaver believes that 80 per cent. of all cases occur in males. Of 1577 cases of appendicitis collected from the annual reports of the City Hospitals of Berlin, 949 were males and 629 females. In practically all of the cases in females that had come under his observation mistakes in diagnosis had been made either by himself or by the attending physician. Almost all of the attacks had occurred at or about the menstrual term, and most of them had been diagnosticated "inflammation of the tube or ovary." In two cases in his own series the appendix and the right tube and ovary were involved; in two others the appendicular trouble was complicated with diseased kidneys. Two patients suffered with recurrent appendicitis and attacks of renal colic before or after operation for the removal of their appendices. He had records of 49 cases of appendicitis seen within the last sixteen months, 29 of them being males and 20 females. During this period he had operated on 17 males and 14 females. The author then detailed 13 cases which were reported to emphasize the difficulties attending diagnosis. In several of them systematic treatment directed to the genitalia had been carried on without giving any benefit whatever, while the removal of the appendix effected a cure. In others the ovaries and tubes had been removed, and still the symptoms persisted until relieved by appendectomy. The author is convinced that the great disparity in the statistics as to the relative frequency of appendicitis in the male and female is due in a great measure to mistakes in diagnosis. It is much more difficult to make a diagnosis of appendicitis in the female than it is in the male. Sufficient stress has not been laid upon the fact that appendicitis in women usually occurs at or about the menstrual period.

Dr. J. B. S. Holmes of Atlanta detailed three interesting cases of appendicitis in females, which illustrated forcibly the necessity of always examining the appendix when the abdomen of a woman is opened for any cause.

Dr. Hal C. Wyman of Detroit cited a case of extra-uterine pregnancy in which he removed a fetus that had apparently died at the end of the seventh month of pregnancy. The operation was done thirteen months after the appearance of the first symptoms of pregnancy. The appendix was found intimately blended with the fimbria of the right tube. The left tube was also somewhat diseased and he doubted its perviousness. It was not removed because there was no particular indication for its removal. The right Fallopian tube, however, was involved with the appendix by dense inflammatory adhesions, and it occurred to him that in consequence of that blending the impregnated ovum had escaped. With this experience some of the cases of extra-uterine pregnancy might possibly be justly charged to adhesions between the fimbria and the appendix. The appendix was three and a half inches long; it had a number of scars; it was much hardened at its end and at the point where union with the fimbria occurred.

Dr. Howard A. Kelly stated that for four years past he has made it a rule at the Johns Hopkins Hospital to have stated in the history the exact condition of the appendix. During this period he has removed 150 appendices. Of this number 60 were involved in pelvic inflammatory disease. He found the appendix adherent to myomata in 12 and to ovarian tumors in 9. He found carcinoma of the appendix secondary to ovarian carcinoma, without any traceable macroscopic relation in 1 case, and primary carcinoma in 1 case. He found tuberculosis of the appendix secondary to tuberculosis in the tubes and ovaries in 3 cases; in the remainder of the cases calculi, cystic diseases, and uncomplicated appendicitis. If, in opening the abdomen for any pathological condition, the incision is sufficiently large, he would examine the appendix.

Dr. Lewis S. McMurtry mentioned a case in which he had enucleated an ovarian cyst in a woman aged thirty years. She had had a typical acute perforative appendicitis, followed by septic symptoms, which was quite limited in the area of peritoneal involvement. When the abdomen was opened it was found that the appendix, instead of perforating the general peritoneal cavity, pierced the ovarian cyst, in that manner limiting the infection to the ovarian cyst and saving the life of the patient.

Dr. William P. Nicolson of Atlanta called attention to the coincidence of disease of the appendix and uterine adnexa, and cited cases in which symptoms for years had been ascribed to uterine or ovarian trouble, but operation disclosed the fact that the appendix was solely at fault.

Dr. George Ben Johnston expressed the conviction that chronic appendicitis is quite as frequent in the female as in the male. He believes, however, that fewer cases of the fulminating form of the disease are seen in the female than in the male. He has observed numerous cases of chronic appendicitis associated with movable kidney in females, and it is sometimes difficult to determine which is the cause of the distress for which the patient consults a surgeon. The coexistence of the two conditions is so frequent in his practice that oftentimes he keeps patients under observation for days, perhaps weeks, to determine which is the more distressing condition.

Drainage in Abdominal Surgery.—Dr. J. W. Long of Salisbury, North Carolina, said that the chief purposes of this procedure are to drain away existing septic material; to afford an exit for the sepsis; to provoke adhesions and thereby wall off weak spots; to keep the peritoneal cavity free of blood and other fluids; to allow of a more certain knowledge of the conditions present. Gauze drains are sometimes employed as tam-

pons to control hemorrhage. These features of drainage were discussed in the order given. After a historical résumé the author spoke of the objections to drainage. These were as follows: (1) Drainage is deceptive. (2) Cases not drained do better. (3) Drainage is neither scientific nor workmanlike. The last statement was made with an apology and due deference to those distinguished gentlemen who drain most of their cases.

Dr. Manning Simons of Charleston, South Carolina, agreed in the main with the observations of Dr. Long, but said there are some surgeons who would not admit that draining in suppurative cases is an evidence that something has been left which ought to have been removed, or that the surgeon had done something that he ought not to have done. He apprehends that there are many cases in which suppuration is not confined to the tubes, but has diffused itself more or less over the pelvic and abdominal cavities. The surgeon's conscience would scarcely, in such a case, prompt him to close up all avenues for the escape of reaccumulated fluid from the cavity. Drainage is applicable to such cases.

Dr. Howard A. Kelly believes that there is a tendency on the part of the profession to drain entirely too many cases. Of his first one hundred cases, eleven years ago, he drained over 80 per cent. of them. Of his last one hundred cases he drained about 1 or 2 per cent. of them. He would drain cases of localized sepsis in which he could not remove the entire septic area.

Dr. W. E. B. Davis referred to drainage in general septic peritonitis, and said it was impossible to lay down any fixed or definite plan of treatment because results were uniformly fatal. Much good can be accomplished by first using peroxide of hydrogen in the abdomen in this class of cases, and following it with infusion of normal salt solution, injecting, say a quart, under the skin every three hours. This accomplishes even more than multiple drainage in cases of general septic peritonitis.

Dr. Beverly MacMonagle called attention to drainage in connection with surgery of the gall-bladder and gall-ducts. In all cases in which he had operated on the gall-bladder, he had found it was necessary to drain. In so doing it was almost impossible to drain it in such a way that a certain amount of fluid would not escape into the peritoneal cavity, hence the necessity of using a small drain of gauze in the peritoneal cavity itself.

Atresia of the Vagina.—Dr. George H. Noble of Atlanta described a flap operation for the relief of this condition, saying that he had operated successfully in several cases by the plan he had outlined.

Technical Improvements in Surgery of Stomach for Carcinoma.—Dr. Willis G. Macdonald of Albany read this paper. Reference was made to the early history of operations for the relief of this disease. The technic employed by Billroth in his first pylorectomy was the technic of operations done by most surgeons for a number of years, with very slight modifications. This earlier operation presented many technical difficulties in its performance. The matter of the adjustment of the resected stomach and the duodenum at the completion of the operation was frequently defective. Secondary perforation at the line of suture with subsequent peritonitis has been a frequent cause of death associated with this earlier form of operation. Before giving a more accurate description of the preferable forms of surgical intervention in carcinoma of the stomach, the author considered the limitations of early and late exploratory abdominal section in the treatment of this condition. Any one, or a combination of symptoms, is a sufficient indication for operation: (1) A chronic gastritis which is progressive in character under proper dietetic, medicinal and physical treatment. (2) A loss of gastric motility. (3) Progressive diminution of gastric peristalsis. (4) A diminution of free hydrochloric acid, progressive in character. (5) Emaciation of the patient under forced diet. (6) Reduction of the hemoglobin in the blood, progressive to 65 per cent. or under, and a moderate leucocytosis. The widest extirpation is demanded in carcinoma of the stomach. The author called attention to the careful investigations of Cuneo and Most with relation to the distributions of the lymphatics and lymph-nodes as associated with carcinoma of the stomach. All surgery for carcinoma involves the removal of lymph-nodes as far as is compatible with adjacent anatomical structures. In a complete pylorectomy it is desirable to remove the lymphatics along both curvatures of the stomach as well as those lying behind the pylorus. As a rule the duodenum is not extensively involved in pyloric carcinoma, although a few observers have found infiltration of Brunner's glands in the upper portion of the duodenum. There is little justification for the total extirpation of the stomach in the majority of cases, and the probability of cure will not be greater than surgical resection. The old rule of cutting one centimeter beyond all evidences of carcinomatous infiltration is not wide enough. Personally the author feels that the line of excision in the stomach should be at least three centimeters from the border of the last palpable infiltration, and in the duodenum at least two centimeters from the most dependent portion of the growth. The recently-devised clamps of Kocher were presented for inspection, also diagrams showing their mode of application. By the application of these clamps to the stomach and duodenum with a little care all dangers of sepsis from the stomach and duodenum are avoided, and the rapidity with which a pylorus may be resected is greatly increased. Very little time is required to close the ends of the stomach and duodenum with a running catgut suture involving all the coats. This again is invaginated within the stomach and the caliber of the duodenum and the stump bur-

ied by rows of Lembert sutures. The manner of performing the subsequent gastro-enterostomy lies largely with the preferences of the surgeon doing the operation. The speaker's earlier gastro-enterostomies were done by the Wolffler method of attaching the jejunum and the anterior wall of the stomach. It appears to him that the two fatal cases in which he applied that method were due to regurgitation of bile into the stomach and persistent vomiting following operation. Some two years ago he began employing Von Hacker's method of attaching the jejunum to the posterior gastric wall with a reanastomosis between the duodenum and the jejunum. The results of this method of operation have been most satisfactory. During the past year he has employed it eight times with seven recoveries. For the most part, the anastomosis between the jejunum and stomach has been made by the suture method, although a number of surgeons have been quite as successful in the employment of the Murphy button. For the secondary anastomosis the author has uniformly used a Murphy button of moderate size. The anastomosis by this method requires very little time for its performance and can be readily completed in five minutes. When an operation has been carried out by this method to its completion the following advantages were claimed for it: (1) Freedom from contamination of the wound by stomach-contents. (2) Accessibility of the neighboring lymphatic nodes for extirpation. (3) No subsequent danger from suture perforation. (4) Freedom from loss of blood. (5) The great saving of time required for the operation. Lateral anastomosis can be readily accomplished by a variety of methods. The immediate mortality for the operation of pylorectomy is an interesting study. Ewald condemned the operation because of its great mortality, 73 per cent., and until 1888 the mortality was somewhere in the neighborhood of 60 per cent. The mortality of Billroth was 45 per cent., of Mikulicz 30 per cent., of Kronlein 25 per cent., of Maydl 16 per cent., and of Kocher 8.7 per cent. Mayo Robson in a study of 572 cases, collected from various sources, finds an average mortality of 30.4 per cent. Guinard found that in 148 cases of pylorectomy with end-to-end anastomosis, deaths were 56, or 37.8 per cent., and in 64 cases of pylorectomy with subsequent lateral anastomosis, there were 10 deaths, or 15 per cent. This showing has been equally favorable in the experience of others.

Menstrual Condition of the Average Girl in Average Health.—Dr. George J. Engelmann of Boston presented an interesting statistical paper on this subject, the facts presented by him being culled from the records of 4873 cases from high and normal schools, colleges and department stores, girls between fifteen and twenty-six, the majority between eighteen and twenty-two, in rather better than average health, in good health, and in numbers sufficient to admit of positive deductions as to what may be termed normal or average menstruation. In brief, the menstrual period proper is intensified by the increase of all vital energies, followed by a depression which appears with the coming of the flow. Under ideal conditions, and in perfect health, the physiological status is such that this epoch, preceded by a day or two of heightened activity, is marked by a moderate lassitude, mental and physical, the flow persisting for from four to five days, and recurring at regular intervals of about twenty-eight days. It is a period of heightened susceptibility that quickly records any variation from the normal; excitement or exertion, or fatigue, mental or physical, are promptly reflected by variation in the function, and in our every-day life such disturbing elements constantly occur, so that conditions actually existing vary greatly from this ideal. The average period of the average girl in average health presents very different features: Regularity in 50 per cent. of the cases only; recurrence every twenty-eight days in 30 per cent., varying most frequently from twenty-six to forty-two days, 45 per cent. being over twenty-eight. The duration varies from two to seven days, average 4.6; from 66 to 70 per cent. suffer more or less, the number of sufferers varying according to age and nature of occupation, between 30 and 90 per cent. Lessened ability for exertion, mental or physical, is admitted by 60 per cent. Some few are habitually incapacitated from work and 30 per cent. occasionally. The function of the condition of the girl in good health, under modern conditions of life, is by no means an ideal one, and in fact the functional health of the American girl, the coming mother of American men, is far from what it should be by right of inheritance and surroundings. This fact physicians must recognize, and upon them and educators devolve the duty of study and correction of the evil.

Operation for Marked Prolapse of the Rectum in Women.—Dr. J. Wesley Bovée of Washington, D. C., described an operation for the relief of this condition. In his case marked prolapse of the uterus was associated with hemorrhoids and great procidentia of the rectum in a woman to whom the uterine appendages were of little value. No simple operation would have relieved the rectal condition while the uterus was in such a state of prolapse, and *vice versa*. These conditions caused him to resort to the unique radical procedure which can be best described by narrating the following case: Sister V., thirty-five years of age, had been treated unsuccessfully a number of years for prolapse of the rectum, uterus, and hemorrhoids. When she came under the speaker's care she was suffering from large internal and external hemorrhoids, and a protruding roll of fully three inches of the rectum that was thickened and much discolored. The uterus was of normal size, with its cervix just behind the pubes, and the fundus very low posteriorily. A few days later, March 6, 1900, operation was done. The hemorrhoids were first removed, then the ab-

domen was opened by the usual subumbilical median line incision. The left ovary was about three times its natural size, and largely consisted of numerous cysts. The appendages were removed and the uterus firmly fixed to the abdominal wall by four interrupted, strong catgut sutures, which passed through a considerable portion of the uterine fundus at the top, and the principal fascia of the abdominal wall on either side of the incision. The rectum was drawn upward until it was fairly tense, and so held by an assistant until it was sutured to the cul-de-sac and posterior wall of the uterus up to the abdominal wall. This was done by a running catgut suture. It completely divided the retrouterine pelvic cavity into two equilateral ones.

Carbolic Acid in Surgery.—Dr. Seneca D. Powell of New York read this paper. In 1894 he first became convinced that he could control the action of carbolic acid by means of alcohol under all circumstances. At that time he used it in its full strength of 95 per cent. in an abscess cavity upon a patient suffering from suppurative appendicitis. Since then he has extended its use to all cases in which he has had to fight disease due to microbic infection, and he is now prepared to assert its safety and reliability, when properly brought in contact with an infected surface. He bases his statements on the results of treatment of hundreds of cases which have come to his clinic at the Post-Graduate Hospital. The speaker has used carbolic acid for years in the treatment of infections and bone diseases in various parts of the body. He recommends its use likewise for erysipelas and abscesses. During the past six years he has treated every phase of microbic disease with this agent, and as early as 1894 hip-joint cases were treated by him with pure carbolic acid and with a large glass drainage-tube. Abscesses, wherever located, can be speedily treated by the injection of, or swabbing with, pure carbolic acid. The size of the abscess, or the amount of surface covered, is not a factor. Only thorough drainage and complete removal of the pyogenic membrane need be considered.

Excision and Irreducible Dislocations.—This subject was discussed by Dr. Willis F. Westmoreland of Atlanta who reported two cases. The first one was an arthrotomy, with excision of the head of the humerus for old dislocation of the shoulder-joint. Miss A. W., white, aged twenty-four years, was thrown from a buggy, right shoulder and elbow-joint being injured. A physician saw the patient, but made no diagnosis. On account of continued pain and lack of motion she consulted a second physician, who recognized dislocation of the shoulder. An effort was made to reduce it, but failed. Upon examination, the author found a subcoracoid dislocation of shoulder-joint, and a badly treated fracture of the external condyle of the humerus. The patient was anesthetized, and an unsuccessful attempt to reduce by Kocher's method was made. Any legitimate force completely failed to even move the head of the humerus. Patient held for operation. A vertical incision, begun just below the acromion process and carried along the inner aspect of the deltoid for about five inches, was made. When the capsule was reached it was split transversely; the head of the humerus was released from its attachments by dry dissection. The head of the bone was then turned out and excised close to the attachment of the capsule. The upper portion of the humerus was pushed up against the glenoid fossa, and the capsule shortened sufficiently to hold it there. In shortening the capsule all excess is inverted and helps to fill the cavity, leaving a very much smaller space to be filled in by adventitious tissue. In this case the slack of the long tendon of the biceps was excised, and the tendon united by mattress and coaptation sutures. The incision was closed, except a small central opening for drainage. There was primary union; and the patient made an uneventful recovery and was discharged with full movements. The second case was as follows: E. D., male, white, aged twenty years. Shoulder dislocated two months ago while boxing. Immediately after the injury a local physician attempted reduction, but failed. Four days later the patient was anesthetized and Dr. Westmoreland made an unsuccessful attempt to reduce by Kocher's method. On the same day an operation similar to the one in the case was performed and patient made an uneventful recovery.

A Plea for the Better Appreciation of the Limitations of Operative Work.—This was the title of the President's Address, delivered by Dr. A. M. Cartledge of Louisville. Every surgeon must be his own arbiter in deciding questions, and the judgment he displays will depend upon his professional learning and wisdom. Methods of surgical diagnosis have undergone striking modifications within the past decade and have influenced operative work. The older surgeon made his diagnosis of abdominal and pelvic lesions slowly; his skill at that time consisting largely of a delicate sense of touch, trained eye to detect asymmetry, keen ears to differentiate sounds elicited by percussion, and methodical investigation of all symptoms, both subjective and objective. The result was, his diagnosis having been made, he next carefully and with abundant time before him considered the advisability of operative intervention. It is as much a part of the knowledge of surgery to know its limitations, or what it cannot do, as to be justly proud and ready to perform that which it has very good reasons to believe will be productive of relief, and cure to the thousands of unfortunates who seek its aid. From every standpoint there is much to be gained by a better appreciation of operative limitations. A plea was entered for more careful diagnoses with an especial view to the detection of attending visceral disease, in short, to try and become more expert prognosticians. There

are two phases of surgical practice alone, the careful observance of which would reduce the mortality of surgical operations so low as to cause us to believe that exactness had almost been reached. He referred to greater care in the detection of kidney lesions and instituting measures to correct this frequent cause of unfortunate operative terminations, and the still prevalent practice of operating upon hopeless cases of cancer. In reviewing the field of abdominal and pelvic surgery it would seem that surgical limitation is most often exceeded and mortality unnecessarily increased in operations for the following diseases: General septic peritonitis, extensive carcinoma of the ovaries, uterus and intestine, and operations upon the gall-passages in long-continued and profound cholemic patients without adequate preparation. He protested against the too frequent practice of operating in these affections. As to laparotomy in cases of general diffuse septic peritonitis, with irrigation and drainage, reports of such cases have appeared in literature from time to time, but the mortality up to the present time of such operations in exaggerated types of the disease is so great as to make it, in his opinion, an unwarranted procedure. He is strongly impressed with the belief that the successful cases reported have been cases of beginning general peritonitis, or of widely-extending, yet circumscribed peritonitis. In closing, the author impressed the importance of carefully preparing cholemic patients before subjecting them to operation with a view of lessening mortality. Another class of cases amenable to the same course of preliminary treatment are those of inefficient renal action.

Excision of External Carotid in Malignant Diseases of Face.—Dr. William P. Nicolson of Atlanta, Georgia, reported two cases. The first patient had a sarcoma of the nose which began apparently as a polypus about eight months before. This was removed several times, but recurred promptly after each removal. When seen a few weeks before the operation this had extended sufficiently to completely obstruct the nose and cause great pain. At the time of operation this had progressed in a few weeks only to such an extent that the growth pressing under the orbit had forced the right eye out of position, and there had been also an extension upon the forehead on the left side. The constant use of morphine was necessary. The right common carotid was excised on October 3d, and the wound healed promptly. The enlargement upon the left side of the forehead broke down, and the large abscess was opened a few days after the operation. The pus from this, or the discharge from the nose, set up a violent ophthalmia, from which the patient suffered for a week or ten days. Two weeks from the day of the first operation the carotid upon the left side was removed, and very soon the symptoms improved in every respect, the patient was relieved of suffering, and the growth not only checked, but it apparently began to recede with the prospects of a material improvement. The second case was one of inoperable sarcoma of the upper jaw of three months' duration and of very rapid growth. In this case the interval between the operations was longer than in the first on account of the occurrence of a severe secondary hemorrhage on the seventh day, which was due to tying the vessel too close to the bifurcation. The first operation in this case relieved the patient of all symptoms caused by the rapidly-increasing pressure, and the growth apparently subsided materially. Sufficient time has not elapsed since the second operation to give much idea as to how much permanent decrease there would be in the tumor. It was claimed that in these cases the patient was doomed if nothing could be done, and this appeared to be the only recourse that offered any hope. He had performed various operations upon the external carotid artery in cases of malignant diseases, having tied the vessel twenty-six times, four of these being cases of double ligation. The operation had not been accompanied by any mortality. Little could be accomplished by simply ligating even both carotids, because the circulation was reestablished so rapidly that the nutrition could not be cut off with any degree of permanence. The operation of excision, as recommended by Dawbarn, seemed to be the only procedure that offered any hope, and while this would not perhaps produce much permanent effect, it seemed undoubtedly true that the lives of patients could be much prolonged and their sufferings greatly lessened.

Autointoxication from Renal Insufficiency With or Without Disease of the Kidneys.—Dr. James T. Jelks of Hot Springs, Arkansas, read this paper. For years he had examined the urinary output for twenty-four hours of every patient who consulted him. This has been a revelation to him and therapeutics based thereon have enabled him to accomplish what he described as marvelous results. Abundant evidence was adduced to show that as the result of faulty elimination by the kidneys, without the presence of disease in these organs, patients may have vertigo, contracted capillaries, cold skin, especially of the extremities, so-called "sick headache," melancholia, palpitation of the heart, interrupted heart beat, various forms of skin diseases, rheumatism, gout, hysteria, epilepsy, and even genuine insanity. Among the remedies used to correct this faulty elimination are squills, milk, rectal, or hypodermic injections of normal saline solution, digitalis or its derivatives, sodium phosphates, sodium salicylate, Vichy water, etc. All of these were used in connection with baths, when it was possible to give them, and the patients were ordered to drink from one-half to one gallon of hot water daily. Twenty-five cases were detailed as having been treated along the lines mentioned, with the most gratifying results.

Dr. George S. Brown, of Birmingham, made (*a*) a supplementary report regarding a case of

biholopaxy previously presented to the Association, and (*b*) a supplementary report with reference to a case of vesicorectal fistula.

Dr. James A. Goggans of Alexander City, Alabama, reported one case of strangulated femoral hernia in a woman, forty years of age; three cases of extra-uterine pregnancy; one case of thoracotomy for empyema, and one case of ovarian cyst.

Life-Saving Measures in Obstetric Work.—R. R. Kime of Atlanta said that leaving out of discussion instrumental deliveries, Cesarean section, symphysiotomy, etc., the most important life-saving measures were saline infusions, medicinal remedies, serotherapy, hydrotherapy, and drainage. In cases of placenta prævia and postpartum hemorrhage saline infusions or intravenous injections are of prime importance, not only to save life, but to lessen susceptibility of infection and hasten recovery.

Pseudomembranous Enteritis and Abdominal Surgery.—Dr. Frank A. Glasgow of St. Louis called attention to this very common disease and urged physicians to study its relations to appendicitis.

Solid Ovarian Tumor.—Dr. John G. Earnest of Atlanta reported a case of solid tumor of the ovary. The patient, Miss M., aged thirty-two years, was seen June 24, 1900. She was a very small woman with a narrow pelvis, had been gradually losing flesh for several months. For months patient had fever every day. There was constant pain in the pelvis; was very despondent, worn out and exhausted. She had a constant watery diarrhea, occasionally interrupted by a few days' constipation, and accompanied by great abdominal distention. This condition, when occurring, was relieved with difficulty, requiring active purgatives and free use of enemas. Nausea was distressing. When the abdomen was opened a mass reaching above the umbilicus was observed. It stood out prominently in the median line, was symmetrical, smooth and hard. It was so firmly fixed that it could not be moved. The dark line down the center of the abdomen was unusually pronounced. Examination by the vagina was somewhat hampered by an unruptured hymen, and tenderness due to the local peritonitis, but he found the cervix pointing forward, low down, and twice its normal size; the uterus retroverted, firmly fixed, and apparently continuous with the superimposed tumor. Rectal examination disclosed that the uterus and tumor were parts of the same body. The fundus uteri could not be reached through the rectum. He believed it to be a uterine fibroid. Patient declined operation until she could go to her home and build up under the care of her family physician. This she did, returning August 1st. On August 3d he opened the abdomen, evacuated a small amount of light-yellow ascitic fluid. The abdominal peritoneum was mottled with dirty brown. The tumor showed the pearly luster of an ovarian tumor. It had so grown that it seemed to be caught under the promontory of the sacrum and was adherent to the pelvic wall. It was enucleated with some difficulty. The pedicle was from the right side and comparatively small. The tumor, when removed, was found to be ovoid in its general outline, with an indenture corresponding to the promontory of the sacrum. It measured twenty centimeters in length, and about fourteen in breadth at the widest point. When cut open its appearance was very much that of an ordinary uterine fibroid, the tissue being quite dense. The cortex was united to the tumor by a thin layer of cellular tissue infiltrated with serum. No microscopic examination was made. At first it was supposed to be a sarcoma, but careful examination showed the fibers to be distinct and arranged in irregular whirls, as in uterine fibroids, and the tissues quite as hard as any fibroid and absolutely solid without a break. The recovery was uninterrupted.

Histogenesis of Ovarian Dermoids.—Dr. W. D. Haggard, Jr., of Nashville gave a verbal abstract of a paper on this subject. He stated that dermoid cystomata of the ovary differ essentially from dermoids in the orbit, pharynx, mediastinum, scrotum, coccyx and elsewhere. The last are unquestionably from inclusions or nipping off of the ectoderm in the development of the embryo, which is similar to the "healing in" of skin in wounds and the subsequent development of a dermoid growth. These structures all contain sebaceous material, hair, plates of bone, teeth, etc., and purely dermal derivatives. Ovarian dermoids contain derivatives of all the mesoderm and enteroderm as well, and hence some adequate explanation other than the inclusion of the skin-forming layer must be forthcoming. All sorts of curious theories have been successively advanced. The virginal pregnancy idea was succeeded by one which ascribed the origin of these growths to prolonged ungratified sexual desire on the part of the woman. A man who jested at his wife during travail was afflicted with a pregnancy (dermoid) of the thigh. Dermoids of the ovary, however, are akin to the teratomata, and it is to the ovum itself that we must look for a solution of the vexed problem of their etiolgy. Wilms was the first to claim the ovulogenous origin of these growths. Some pathological activity on the part of the ovum in the Graafian follicle is responsible. Bland Sutton found a dermoid of the ovary in a horse when the growth was undoubtedly in the ovum suspended in a large cystic Graafian follicle. Similar cases have been reported in women. Kraemer has recently gone over the entire field and amassed an amazing amount of material that goes far to settle the question, and prove that ovarian dermoids contain products of all the blastodermic tissues, that they cannot spring from an evolutional inclusion simply as dermoids elsewhere undoubtedly do, that they are of ovulogenus origin, a sort of parthenogenesis. In evidence an attempt at formation of nearly all

the organs of the body has been found in the lawless development of these benign growths. Retinal pigment, more or less complete, optical vesicles, a rudimentary pharynx, with an attempt at the formation of an esophageal tube; the sympathetic nerves in the alimentary canal, and, curiously enough, a rudimentary uterus, with branching cells of the cervix and the glands of the fundus; mammæ (one case of which underwent carcinomatous development). An easily-recognized heart provided with valves was found by Johnston; and many other more or less perfectly formed organs and tissues other than dermal have been reported by investigators too numerous to individualize. These data have, as remarked by Clark, dealt a telling, if not fatal, blow to the inclusion theory of ovarian dermoid evolution. The researches of Kraemer and others seem to establish convincingly the ovulogenous theory of their development.

The following papers were likewise read and discussed: "Removal of Cystic Gall-Stones," by Dr. Howard A. Kelly of Baltimore; "Osteo-Arthritis of the Spine," by Dr. Michael Hoke of Atlanta; "Epi- and Hypospadias, with Special Reference to the Operative Treatment," by Dr. W. F. Parham of New Orleans; "Retroflex Incarcerated Gravid Uterus," by Dr. W. A. Quinn of Henderson, Ky.

Much to the regret of the members, Dr. W. E. B. Davis resigned the secretaryship, owing to the pressure of other duties, after having served the Association ably and efficiently from its organization to the present time. A resolution was offered and unanimously adopted thanking Dr. Davis for his efficient services, tireless efforts, and faithful devotion to the interests of the Association during a period of thirteen consecutive years.

Officers Elected for 1901.—President, Dr. Manning Simons of Charleston, S. C.; Vice-Presidents, Drs. George H. Noble of Atlanta, Georgia, and L. C. Bosher of Richmond, Va.; Secretary, Dr. W. D. Haggard, Jr., of Nashville, Tenn.; Treasurer, Dr. F. W. McRae of Atlanta, Georgia.

Richmond, Virginia, was selected as the place for holding the next annual meeting; time, third Tuesday in November, 1901.

Twenty-nine new members were elected at this meeting. After the installation of officers, and the adoption of resolutions of thanks, the Association adjourned.

BOOK REVIEWS.

Contributions from the William Pepper Laboratory of Clinical Medicine. University of Pennsylvania, Philadelphia.

This is a quarto volume of 500 pages made up of 14 contributions from the Pepper Laboratory, all of exceptionally high scientific character. It is a contribution appropriate to the founder.

While most of the papers are technical in character, some stand out as of greater interest from their relation to clinical medicine. Thus, the studies on Leukemia and the Pathology of the Erythrocyte, by Drs. Taylor and Stengel, are practical and timely in view of the rapid strides made in hematology. The Restitution of the Blood Plasma following Intravenous Saline Injections after Hemorrhage, by Drs. A. E. Taylor and C. H. Frazier, offers a practical demonstration of the benefits of this therapeutic procedure. The Influence of Immoderate Water-drinking upon Metabolism and Nutrition, by Dr. D. L. Edsall, is a capital study of this frequent procedure and strikingly demonstrates the evils of the habit. We would like to see similar products from our large university laboratories.

International Clinics. A Quarterly of Clinical Lectures and Especially Prepared Articles on Medicine, Surgery, etc., by Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D. Volume II., Tenth Series, 1900. Philadelphia: J. B. Lippincott Company.

The present volume of "International Clinics" contains a good representative series of lectures on practical subjects. The editor himself, in the initial article, describes the kromskopic method of reproducing pictures of pathological specimens in their original colors. Every teacher realizes how important a matter for educational purposes such an advance in our present method of illustrating pathology would prove. The kromskop, as invented by Mr. Frederick Ives, is probably the most successful means of photographing in colors yet presented to the public. The results obtained by his method as illustrated in the frontispiece of the book, the kromogram of an ovarian cyst, are certainly very satisfactory.

New York teachers of medicine are well represented in the present volume of the clinics. We note among the contributors the names of Dr. Andrew H. Smith, Dr. Alexander J. C. Skene, Dr. J. Riddle Goffe, Dr. William H. Katzenbach, Dr. Robert T. Morris, and Dr. Charles Warrenne Allen.

Dr. J. W. Ballantyne, of Edinburgh, contributes an important article on the therapeutics of the unborn infant, and Dr. J. C. Wilson, of Philadelphia, a clinic on atypical enteric fever of peculiar interest at the present time when practitioners in many parts of the country are being confronted with unusual forms of typhoid fever. Dr. Andrew H. Smith opportunely discusses the inadequacy of the physical signs as indicating the gravity of pneumonia, and Dr. Charles J. Aldrich, of Cleveland, contributes a very practical clinic on compressed air illness, or caisson disease, with which he has had considerable experience during the construction of the new water tunnel beneath the bed of Lake Erie.

As a whole the present volume of "International Clinics" is an excellent mirror of hospital practice in various parts of the medical world

and its perusal should form some compensation to the busy country practitioner for the opportunities he might have if situated in a medical center.

Operative and Practical Surgery. For the Use of Students and Practitioners. By Thomas Carwardine, M.S. (Lond.), F.R.C.S., Assistant Surgeon, Bristol Royal Infirmary. 8vo., 661 pages. Illustrated. Bristol: John Wright & Co.

"I have thought that I may for once leave the science of surgery alone—it is, indeed, well able to take care of itself—and, instead of the science, I shall speak of the art." In this quotation of J. Greig Smith's is embodied the true point of view in and scope of Mr. Carwardine's text-book of surgery. Beginning with a section on general considerations, the author therefrom directly passes to a discussion on bandaging, dislocations, and splints and fractures. This portion is an admirable statement of the practical points connected with the subject. Section III. is a lucid summary of the art of bone, joint, nerve and tendon surgery. Ligation of the principal arteries with special reference to anatomical details is also treated of in the same section. Following this come the discussions of regional surgery in its varied aspects. Finally, the book terminates with a very full index which will be particularly valuable in looking up special points. The arrangement is otherwise so excellent that little difficulty ought to be experienced in finding the main points relating to any given subject.

In looking over the book one readily sees that in the matter of technical steps of various operations the author has kept pace with the movement of the time. In the matter of aseptic technic, however, the author evidently relies too much on antiseptics and not sufficiently on heat as a factor in sterilization. Outside of this one point the book will be found an excellent guide to the art of operative and practical surgery.

Clinical Lectures on the Urine and Urinary Diagnosis. A Clinical Guide for the Use Practitioners and Students of Medicine Surgery. By J. Bergen Ogden, M.D., Instructor in Chemistry, Harvard University Medical School, etc. W. B. Saunders & Company, Philadelphia.

Conceived in a thoroughly modern spirit the present volume on the examination of the urine is one of the best that has been presented to the student and practitioner of medicine. There remains little else for the reviewer to say as the subject of urinary analysis is one so thoroughly exploited by numerous publications. The text is clear and well written, the illustrations numerous and, for the most part, well executed, many of them in color. We regret to see, however, so many of the crude, old, time-worn illustrations. The modern methods of chemic spelling are not followed, but this perhaps is an advantage rather than a blemish. The work is thoroughly "up to date" and can be heartily recommended.

The Care of the Child in Health. By Nathan Oppenheim, A.B., M.D., Attending Physician to the Children's Department of Mt. Sinai Hospital. Three hundred and eight pages. New York and London: Macmillan & Co., 1900.

Dr. Oppenheim's work on the "Medical Diseases of Childhood" was written for his fellow practitioners. This book is written for his patients, or rather, to be put into the hands of mothers, and to be boiled down for nursery-maids. It is a good, sensible book, in the form of a series of little essays, beginning with the child before he is conceived, and laying down the law very gracefully, but firmly, to the young women who are to become the mothers of the race. The same young women are advised during their pregnancy what to eat, to wear, to do, and to think in order to bear strong, healthy children. Then, presupposing a more or less prevailing ignorance on the subject, the young mother is carefully instructed how to feed and clothe and bathe her child, how to teach him habits of health, and to develop his body to its fullest capacity. It is a good book, and can be safely recommended to physicians to recommend in turn to the up-bringers of children. It is perhaps a trifle too general, and will serve as a book for mothers to lend to their less enlightened friends, rather than a book that is used for steady reference. It contains only what every mother ought to know by education and experience; but as many of them lack that, it will doubtless fill a need.

Laboratory Directions for Beginners in Bacteriology. An Introduction to Practical Bacteriology for Students and Practitioners of Comparative and of Human Medicine. By Veranus A. Moore, B.S., M.D., Professor of Comparative Pathology and Bacteriology, New York State Veterinary College, and of Bacteriology, Cornell University Medical College, Ithaca, N. Y. Second Edition, Enlarged and Revised; 143 pages. Boston: Ginn & Co., 1900.

The author begins with general directions as to stocking a laboratory, cleaning glassware, and preparing culture media and the staining solutions. Then follow directions for the making of tube, plate, and Esmarch roll cultures, the making and staining of cover-glass preparations, and the methods of examining these. The properties of bacteria, such as gas-production, motility, and spore-formation are considered, and the more common pathogenic organisms are studied individually. Chapters are devoted to the Widal serum test, isolation and identification of bacteria, studies in disinfectants, milk, water, and animal inoculation for diagnosis. The author has condensed a large amount of practical bacteriology in the form of exercises into a convenient and compact work. It is a very simple guide however.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, DECEMBER 1, 1900. NO. 22.

ORIGINAL ARTICLES.

WHEN SHALL WE OPERATE IN APPENDICITIS.[1]

BY FRANK E. BUNTS, M.D.,

OF CLEVELAND, OHIO;

PROFESSOR OF PRINCIPLES OF SURGERY AND CLINICAL SURGERY, MEDICAL DEPARTMENT, WESTERN RESERVE UNIVERSITY.

IN the present state of medical opinion it is absolutely impossible to lay down any rule on this question which will be, or perhaps ought to be, followed by the profession. Such a rule is not yet and probably never will be formulated. Yet it is a matter for congratulation that we are able to see a little light in the chaos of opinion and find that after all we are not so far apart as some would have us believe. It has occurred to me sometimes that some of us are not absolutely sincere in our statements of our position. Some say "operate" in every case without any qualifications, and I am sure they do not do it. Others are opposed to all operations, and so express themselves, and yet I know there are cases where even they will consent to, or urge, an operation, and among those who fancy that they have a definite rule by which they decide to operate or not to operate, it is not so much the rule as it is an indefinable impression gained from experience which oftentimes settles the question as to when they shall operate.

It is possible to divide the cases of appendicitis into a group of classes each of which, perhaps, deserves a separate consideration. (1) Cases recognized as appendicitis at their inception, of moderate severity of symptoms. (2) Cases recognized as appendicitis at their inception and characterized by great intensity of symptoms. (3) Cases not recognized as appendicitis until several days have elapsed, symptoms then becoming pronounced. (4) Cases recognized as appendicitis in which the surgeon is not called until the symptoms have begun to abate as indicated by diminution of pain, temperature and pulse-rate. (5) Cases in which delay has resulted in general peritonitis or septicemia. This classification, although essentially arbitrary, seems to me to be a fairly practical one, at least it is one that shapes itself in my mind as I examine a case of appendicitis, and, since I realize that each operator has his own peculiar views regarding the question of operation, I shall not attempt in any way to make their views harmonize or to present them for consideration, but rather add my own views, so far as it is possible for me to formulate them, to what has already been written.

1. Cases recognized as appendicitis at their inception and of moderate severity of symptoms. These cases are most elusive and deceptive. It must be clearly recognized from the start that, however mild may be the onset, there can be no possible way of telling when the case may become alarming and no physician or surgeon can tell more than one totally out of the realms of medicine when an appendix may rupture. A few days or a few hours may be sufficient to determine gangrene of the appendix.

I believe it is in this class more than any other that the physician and surgeon differ. Realizing fully the responsibility attached to an opinion in these cases I believe that if the conditions for operation, that is, the surroundings, assistants and operator, are favorable, immediate operation will result in the greatest number of cures. Personally, I cannot recall a case in a series, now becoming somewhat extensive, when under such circumstances I have lost a patient. On the other hand, I am sure, from the examination of the appendices removed, that while some of them would undoubtedly have gone on to recovery, perhaps never to recur again, some of them were already at the point of gangrene, or of rupture, or were filled with concretions or pus which foretold a severe or fatal attack if left alone.

There is one consideration which has contributed not a little to the desire on the part of the attending physician to delay the operation, and that is the belief that if the patient recovers it is much better to operate between attacks. It is to be regretted that this belief should have received the wide credence which it has, for it certainly has been a stumbling-block of no small magnitude. I believe that any case of appendicitis can be operated on at the beginning of an attack quite as successfully, indeed, often more successfully than between attacks, and, if it resolves itself into a question of operating at the beginning of an attack or between attacks, then the former should be chosen. Why? (1) Because no one can positively say whether the patient will live through the present attack. (2) Because each succeeding attack when completed leaves the appendix by reason of adhesions, lymph deposits, and increased abnormal relations, in a more unfavorable condition for operation.

I feel very strongly that this fact cannot be too much emphasized and the sooner the glamor of operating between attacks and its fancied ease are removed the greater will be the safety of the patient. Suppose that in a case under this group the consent of the patient or the attending phy-

[1] Read before the Cuyahoga County Medical Society, October, 1900.

sician cannot be obtained for an operation, is there any way in which we can follow the case and give a reasonable estimate as to its progress? In many cases, yes. In some cases, no. Some will change so rapidly for the worse that the patient will be beyond the reach of surgical or medical aid in a few hours. In the less acute and more favorable cases, however, we can follow the progress in most instances very accurately and intelligently by means of the white blood-count. An increasing leucocytosis in appendicitis is, I believe, sufficient evidence of increased inflammation and probably pus formation, to justify the urging of an operation, while a stationary white blood-count will almost certainly indicate the subsidence of the inflammation and a favorable outcome may be almost safely predicted. To variations of temperature I attach but little importance, but an increasing pulse-rate is a matter of serious moment and deserves careful consideration, for it is probably the early indicator of septic intoxication or possibly of septic infection.

2. Cases characterized by great urgency and intensity of symptoms. In these cases I believe great pain to be the most characteristic and important symptom and I have no hesitation in saying that they should be operated upon at the earliest possible moment; fortunately for the patient his acute suffering usually persuades him not to delay in acquiescing to an operation. It is folly to wait under any pretext in these cases. It goes without saying, of course, that some might get well of themselves, but the very intensity of the symptoms leads us to fear rapid progress and perforation may take place too early for Nature in her conservative efforts to wall off the diseased appendage and permit general peritoneal infection.

3. Cases not recognized as appendicitis until several days have elapsed, symptoms then becoming pronounced. Even in these cases it seems to me that operation is indicated, although it may not be so urgently demanded. The time which has already elapsed will probably have been sufficient to wall off the appendix and prevent the spread of infection, and when strenuous objection is urged by the patient or the attending physician it may be considered reasonably safe to wait long enough to determine by means of the white blood-count whether the inflammation is progressing or diminishing. If the former, operate; if the latter, delay is under such circumstances permissible.

4. Cases recognized as appendicitis but which the surgeon does not see until the symptoms have begun to abate as indicated by diminution of pain, temperature and pulse-rate. This class of cases is not infrequent, and I recall at least five such in the past year in which I have advised against immediate operation and recovery followed in each. Why not urge operation in all these attacks? Why wait and operate between attacks? (1) Because the advantages of an immediate operation, absence of adhesions, etc., are lost. (2) Because the patient's general condition is lowered and a few weeks of convalescence and recuperation will put him in a better condition to withstand the slight shock of operation.

Would I operate in all these cases that had been allowed to reach the stage known as between attacks? No. What then governs my position? As near as I can formulate it, it is this: If the preceding attacks have been severe ones, I urge it. If the patient expects to travel or go away to school, or otherwise put himself in a position where immediate aid under favorable surroundings might not be secured, I urge it. If the patient is not sufficiently intelligent to appreciate the importance of the condition and feels that because he has gone through one attack he will safely go through another, I urge it; but if the patient is intelligent, if his circumstances are such that he can obtain medical aid at any moment and if he will agree that at the first onset of the disease he will submit to an operation, then I do not insist upon an operation between attacks. Why? (1) Because he may never have another. (2) Because the next attack is readily recognized and the diagnosis made very early. (3) Because an immediate operation is in my opinion practically as safe and as easy as one between attacks.

5. Cases in which delay has resulted in general peritonitis or septicemia. What must the surgeon say in answer to an appeal that he operate in these cases; an operation of last resort, "the only chance for the patient." Well, if he were to answer according to his wishes, according to the best interests of his reputation and his disinclination to shoulder a responsibility that belongs elsewhere, I believe he would resolutely say "no." I must confess I have been greatly tempted to take the position advocated by one of America's greatest surgeons at the recent meeting of the American Medical Association and say in these cases, so unfavorable in their outcome, so sure to die, that operation is hopeless, for the operation gets the credit of killing the patient and undeserved discredit is insensibly cast upon a conservative operation, for unfortunately, even yet to the average person out of the medical profession, appendicitis, grave or mild, is still appendicitis, and the last thing done is the cause of death.

A MEDICAL VIEW OF THE TREATMENT OF THE CECUM AND APPENDIX.

By A. L. BENEDICT, M.D.,
of Buffalo, N. Y.;

Professor of Physiology and Digestive Diseases, Dental Department, University of Buffalo.

While this paper deals particularly with therapeutics, some consideration of pathology, etiology, prognosis and diagnosis is necessary as a basis. Without quoting in detail any of the various surgical classifications of appendicitis, prompt and radical operation should be urged in all instances in which sepsis is the essential con-

dition or the essential danger. These include perforative appendicitis, gangrene, circumscribed abscess (the old perityphlitis or, more critically, paratyphlitis) and also strictured, distorted and adherent appendices and those that are the seat of such bacterial infiltration and ulceration that spontaneous cure cannot be expected. On the other hand, mild cases of catarrhal appendicitis, without peritonitis or more than superficial ulceration, in short, cases in which the appendix is involved simply as a part of the cecum, are amenable to medical treatment. According to the judgment of most conservative physicians, it is scarcely justifiable to perform the radical operation of amputating the appendix as a means of prophylaxis, unless there is reasonable probability of a recurrent inflammation, while removal of any organ is not treatment.

Except that the anatomical relations of the appendix render any septic condition of paramount danger, a close analogy may be drawn between it and the tonsil. Both are vestigial organs, rich in lymphoid tissue and, as a consequence, points of lessened resistance and particularly prone to interstitial inflammation ending in suppuration. In determining whether to use destructive or conservative measures in dealing with the inflamed tonsil, we consider not only the inflammatory reaction, but whether the tonsil is primarily the seat of inflammation or whether it simply participates in a general pharyngitis. Likewise, it is important to determine whether the appendix itself is at fault or whether this part of the cecum shares in a more general inflammation of the head of the colon. I shall not delay to show that typhlitis is a real disease. Its existence is demonstrated both clinically and by necropsies and the burden of proof rests with those who, in the reaction from the earlier error of ignoring the appendix, have implicitly claimed that the cecum was a part of the alimentary canal exempt from inflammation.

The bacteriologic study of numerous cases of appendicitis, as well as of diarrhea, dysentery (non-amebic), colitis, even of cholecystitis, has shown that the bacillus coli communis is the germ chiefly concerned, although it is normally a comparatively innocuous inhabitant of the bowel—not, however, a necessary parasite.

Taking cold is a time-honored factor in all inflammations and we must admit that, especially in the form of going for hours with the feet cold and damp, it may be a contributing factor in producing a typhlitis. Traumatisms are infrequent causes. The repeated, slight traumatisms of muscular action have been overrated. A recent article, with sublime ignorance of anatomy, has even attempted to incriminate the sartorius and to establish a greater liability to inflammation of the appendix among tailors and others who sit cross-legged. The iliopsoas, in hill-climbing, bicycle-riding, etc., undoubtedly causes some indirect friction against the appendix and probably aids in the production of inflammation when other causes are present. Edebohls has emphasized the connection between movable right kidney and appendicitis. In about five hundred persons examined for movable kidney, I have found only one case of this association. In about ten per cent. of the cases examined, at least one kidney was found movable. This high percentage is due to the fact that about two hundred of the series were parous women who had some uterine displacement. In about forty cases of appendicitis, in which thorough palpation was practised, either before or after the attack, no renal movability was found.

The rather frequent invasion of the cecum and colon in typhoid, the occasional occurrence of a genuine appendicitis in this disease, and the infrequent finding of a tuberculous appendix, indicate a connection with specific bacteria but, as a rule, the prime infectious element is the colon bacillus.

Coarse, indigestible food is not a very direct cause of inflammation of the cecum and appendix, on account of the distance from the mouth and because the normal intestinal mucosa is not particularly susceptible to mechanical insults. The presence of seeds and other foreign bodies in the appendix has been shown to be exceedingly rare, some of the older statistics being misleading, because concrements were mistaken for true foreign bodies. However, there seems to be, especially for children, a combined mechanical and toxic action of peanuts that determines an inflammation at this locality. If, however, a typhlitis is once started, corn, raw starch, and indigestible parts of fruits may continue the irritation of the mucosa and may bring about relapses.

A careful and impartial study of typhlitis and appendicitis will show that, in practically all cases, we may make out one general etiologic factor, *viz.*, some condition of the alimentary canal favoring a virulent development of the colon bacillus. In a small majority of cases, a history of chronic constipation can be elicited and the persons attacked are, in general, either those of sedentary habits or those guilty of serious infringements of dietetic hygiene. Imperfect mastication, eating between meals, the use of excessive quantities of fermentable or putrescible foods, such as sugar and tainted meats, respectively, often the positive account of symptoms of gastro-enteric fermentation, flatulence, etc., are frequently noted in the history. Many restaurants make a practice of buying meat, oysters, fish, etc., that are on the verge of rottenness, and of disguising the flavor by frying or serving with rich and highly-seasoned sauces. Sometimes a special article of food, such as pork, canned lobster, baked beans, cabbage, or the ingestion of a large quantity of alcoholic beverages may be incriminated.

While it is an easy matter to quote prognosis tables from the periodical literature, the different series differ so much in severity, according as they are collected by different observers, that no

accurate comparison can be instituted. However, the following general statements are borne out by all comprehensive reports:

1. Patients operated on at the very beginning of symptoms pointing to the appendix almost all recover. The slight mortality is no greater than would be expected from errors of technic, occasional general weakness, accidents of anesthesia, etc., if the operations were performed as vivisections without local disease.

2. Up to about the third day, unless the cases are fulminating, even severe cases of appendicitis show a low mortality, varying up to about fifteen per cent.

3. After the fourth day the patient has either passed the immediate need of operation or it is too late to operate except with the idea of affording the benefit of a desperate chance. Few surgeons advise amputation of the appendix at this stage, the object being to evacuate pus or to attempt to limit the septic process by suturing, packing, etc. Some surgeons openly advocate the brutal policy of refusing to operate under any circumstances at this time, so as to keep their statistics of results favorable and to teach medical men to refer such cases for early operation.

4. If we include as appendicitis all cases with symptoms calling attention to McBurney's point, that is, all on which extremely radical surgeons would operate, if they had the chance, the results of medical and surgical treatment are about equal. It is to be noted that the extremists of either side are anxious to include the mildest cases of typhlitis as genuine cases of appendicitis.

5. A good many cases which have been "cured" by medical treatment, relapse. Sometimes these relapses are severe and even fatal, sometimes we are justified in doubting whether they are more than slight attacks of colic, due to dietetic indiscretions and the importance of which has been overestimated by the surgeon.

6. On the other hand, some cases that have been "cured" by amputation suffer from recurrences which would be considered attacks of appendicitis if we did not know that the appendix was lacking. Not a few cases for supposedly primary appendicitis have been performed at which the appendix could not be found. Scott, in the *Bulletin of the Cleveland General Hospital*, April, 1899, analyzes five such cases and holds that insufficient search was made for the appendix. Eitel, in the *Journal of the American Medical Association*, July 29, 1899, states that only six indisputable cases of congenital absence of the appendix have been recorded.

7. Radical operation, although not very dangerous immediately, may be followed by hernia. Francis B. Harrington reported to the American Surgical Association, 1899, the results of 236 cases, 11½ per cent. were followed by true hernia, 27 per cent. more by punctiform hernia or bulging of the scar. Wounds, however, that could be closed primarily, presented only 3½ per cent. of true hernia.

It will be seen from the consideration of these generalizations from statistics that a little manipulation of figures may serve to uphold almost any extreme view. For instance, we are asked in all seriousness to submit every case that presents the initial symptoms of typhlitis or appendicitis to operation for amputation of the appendix. Such a course would, undoubtedly, improve the mortality tables of this operation just as the tables of amputations of legs would be much more favorable if amputation were performed on every person who sprained his ankle. But it is scarcely justifiable to vivisect every person who has a colic since the death-rate of all the cases that extreme operators would like to include as "appendicitis" is not as high as the practically inevitable mortality of the operation itself, the anesthesia and the secondary death-rate due to leakage of the stump, to hernia, etc.

If we decide against advising surgery for every case that presents ominous symptoms in the right lower quadrant of the abdomen, and the great majority of the profession have already so decided, the question forces itself upon our attention, Can a satisfactory differential diagnosis be made between typhlitis with merely catarrhal and non-penetrating appendicitis on the one hand, and burrowing, septic and gangrenous forms on the other? There are two ways of answering this question. One is for surgeons and physicians to separate into hostile camps and to attack each other with ridicule and invective if an apparently mild case suddenly develops unfavorably, or if a case operated on within twenty-four hours from the beginning of symptoms dies, or if an operator of judgment and skill is unable to find the appendix, or if he operates with the diagnosis in doubt between appendicitis and ruptured tubal pregnancy and finds an intussusception. None of these are imaginary cases and we all know what difficult problems of diagnosis and prognosis may be concealed within the abdomen. I have seen two clinically typical cases of biliary obstruction prove to be appendicitis and have known a surgeon to diagnose the latter condition, cut down on a normal appendix and, afterward at the necropsy, find a gall-bladder full of pus. Surgeons have warned particularly against the diagnostic errors that may follow the lack of pain and inflammatory reaction of gangrenous appendices and the sudden relief of symptoms that may be due to the rupture of an abscess and the beginning of a septic general peritonitis. But, with all allowance for puzzling cases, it is safer for a man of reasonable skill and experience to fit the treatment to a discriminating diagnosis than to adhere to any routine policy for or against operation. Occasional unfavorable results, due to misconception of the pathologic state are inevitable, but no more so than for any other part of the body.

It is unnecessary to review at length the diagnostic points common to appendicitis and typhlitis. The differential diagnosis between medical

and surgical cases, as previously defined, rests on the following considerations:

1. Temperature. If, when the case is first seen, it is above 102° F., unless a hysteric element or some other extrinsic factor is evident, or if the tendency is upward, operate. A temperature of even 100° F. or 101° F. that continues into the second day, usually indicates operation. If the case is seen late the up-and-down of a septic fever must not be confused with malaria.

2. Pulse. Gangrenous and septic processes, anywhere in the body, are apt to be marked by a rapid, feeble pulse, without rise of temperature; 90 to 100° F. may be taken as an arbitrary safety-line, with due allowance for age, sex, temperament, etc.

3. Blood. Marked leucocytosis indicates operation, but little attention should be paid to leucocytoses of less than 20,000, enough, for instance, to be readily detectable in the stained slide without enumeration. A differential count should also be made in order to be positive that the polymorphous cells are increased.

4. Local tenderness. In acute cases it is not always possible or advisable to feel the appendix. Muscular rigidity of the right lower quadrant of the abdomen is more significant than general or unilateral reflex as indicating a focus of inflammation. It is not usually possible, by palpation alone, to distinguish between the appendix and a tube or ovary. Typhoid ulceration, general typhlitis, etc., produce less muscular reflex than a focal point of disease. Care should be taken not to concentrate the patient's attention on any one part of the abdomen, but to ascertain whether there is any marked difference between the right and left sides, whether the tenderness is diffused or sharply localized, etc. Sometimes the point of maximum tenderness moves with an irritating fecal mass—a favorable indication.

5. Vomiting, with considerable nausea, but almost projectile in type, usually indicates some focal disturbance in which the peritoneum is involved. It may occur in biliary obstruction, in disease of the uterine adnexa, of the appendix, or it may be due to obstipation with expansion of part of the bowel causing tension of the peritoneum, or to some pinching of the peritoneal coat along with external compression of the bowel. Vomiting of this type is not frequent in general inflammatory conditions of the cecum or of the whole colon.

6. Urine. The most important diagnostic constituent is indican. This is to be expected to be present in excess in most cases of typhlitis and appendicitis. If, with other signs pointing especially to the appendix, indican is absent but the urine contains a sufficiency of urea and other solids so that renal failure need not be considered, we may exclude, with some probability, general typhlitis with stagnation and putrefaction of intestinal contents on the one hand and a large collection of pus on the other.

7. The general aspect of the patient and the consistency of the symptoms. One or more symptoms and signs may ameliorate and yet the patient may present indescribable but ominous signs of serious disease. On the other hand, some one indication may be unfavorable but others reassuring. In a recent case that presented leucocytosis and a temperature of 101.6° F. at the first visit, operation was advised, on the evening of the second day from the beginning of symptoms, but during the night the temperature dropped to normal, the pulse being within the danger limit and the leucocytosis diminishing. Operation was postponed, with the advice of the consulting surgeon, and proved unnecessary.

Granted that the case is a proper one for medical treatment, we must distinguish between subacute and chronic forms, the acute forms belonging to the surgeon. As had already been implied, there can be no separation of typhlitis from appendicitis. The main danger is from the latter, the main and almost the sole treatment must be directed to the former, although the principle of continuity of tissue explains why treatment of one part of the mucous membrane may modify adjacent parts. Our aim is two-fold: (1) To render the intestinal contents as unirritating as possible; (2) to protect and medicate the cecum.

In subacute attacks, as in most comparable diseases, nutrition may be neglected and we may proceed without embarrassment to render the intestinal contents as scanty and as aseptic as possible. All food should be discontinued for at least twenty-four hours, but water may be given freely unless there is some special contraindication such as the occurrence of vomiting after drinking. At the beginning of an attack purgation should be accomplished by the administration of small doses of calomel, every hour, for five or six doses, following with a saline and, in most cases, by a hot enema of approximately physiological salt solution. While magnesium sulphate is a favorite and usually a satisfactory cathartic, there are other salines which are more agreeable to the patient which are less likely to produce nausea and excessive peristalsis and which are just as effective, at least if given in a slightly larger dose. Rochelle salt, Seidlitz powder, effervescent preparations of magnesium citrate and sodium phosphate are in this category. If there is griping, oil of cloves or cinnamon, with or without small doses of atropine, may be used. Heretofore, nothing has been said of appendicular colic. If severe, so that we may reasonably infer the presence of a calculus, it is much safer to resort to surgery. If mild, so that we may suppose that there is present merely a plug of mucus and epithelium, atropine will relieve the spasm while, in small dose, 0.0005-0.0007 mg. (1/100-1/80 gr.), it will not paralyze the smooth muscle. Hot external applications, for instance a spice bag, afford considerable relief, but poultices are perhaps apt to favor the production of pus.

In order to combat the bacillus coli communis —not with the expectation of rendering the intestinal contents germ-free, but of lessening the virulence—an internal antiseptic should be given. Such drugs, for our present purposes, may be crudely classified as follows: (1) Mineral antiseptics: Hg, As, Cu, Ag, Bi, etc.; (2) phenol, resorcin and other slight modifications of the benzol ring; (3) benzoic modifications of this ring; (4) salicylic modifications of this ring; (5) double aromatics, like naphthalin. At the beginning we avail ourselves of both the cathartic and the antiseptic action of mercury, but it is obviously impossible to continue this drug indefinitely. Arsenic is contraindicated in inflammatory conditions of the bowel, although the cecum is situated at such a distance from the mouth that this objection is largely theoretic. Copper is somewhat irritating, but the main objection to its use is its comparative inefficiency. Silver is out of the question for any purpose, except when we can apply it directly to a diseased part. Bismuth is constipating and not actively antiseptic. While invaluable for chronic cases, it is not available for the subacute ones unless considerable diarrhea is present and, even then, its antiseptic action needs reinforcement. The phenol group are either too toxic or too soluble and too readily absorbable for use in this part of the bowel. The benzoic group —and I have tried most of them—are excellent in theory, but inefficient in practice, foul diarrhea, flatulence, etc., continuing in spite of their supposed action. The double aromatics are quite efficient, although naphthalin is disagreeable to patients. All factors considered, I have been best pleased with the salicylic group, especially with salol and salacetol, which are nearly insoluble in the stomach and whose action is reserved for the bowel. The former is perfectly satisfactory for transient use but the phenol constituent is somewhat dangerous, so that for more than a few days' administration, salacetol is preferred. If 0.25 (4 gr.) is given every three hours, a positive antiseptic action can be expected within thirty-six hours, that is, indicanuria will diminish and flatulence will subside. If there is troublesome diarrhea or tenesmus, the latter indicating an involvement of the rectum, a hot injection of boric acid or borax solution, 4-1000, will usually be efficacious.

When nourishment is recommenced, it should consist mainly of toasted bread and soda crackers, cereals and milk. Prepared foods such as malted milks, albumose-milk, and the various combinations of milk and cereal may be employed. Tea, coffee and chocolate should be allowed only sufficiently to flavor the hot milk with which they should be prepared. Meat and meat extracts and teas should be debarred for several days, both because their extractives add to the surplus of effete matter already in the system and because, in their absence, the colon bacillus experiences a lack of pabulum that diminishes its virulence.

This simple but watchful treatment is usually all that is necessary during the subacute attack. A temperature high enough even to suggest the use of antipyretics is an indication for surgical reconsideration of the case nor should antipyretics be used as analgesics, as we do not wish to obscure a significant temperature. The same may be said of pain which cannot be controlled by hot stupes, hyoscyamus, oil of peppermint and similar mild sedatives which act either to relieve intestinal spasm or putrefaction or both.

After a few days, the temperature should have reached normal and the case may be considered in the same category with the ordinary chronic forms of typhlitis and appendicitis. The latter often seek relief for supposed stomach trouble and may be treated in the most pseudoscientific fashion by lavage, etc., for months, without experiencing relief. Only the routine examination of the abdomen suffices to detect the real condition. If, in these chronic conditions, the appendix is markedly enlarged, feeling like a finger under the abdominal wall or if it forms an irregular tumor, or if the patient is so situated that he will not be within easy reach of skilled surgical aid in an emergency, operation under favorable circumstances, in the intermission, should be urged. While, personally, I should not oppose operation but should rather advise it for milder forms, the incurability of chronic appendicitis which has been claimed by some surgeons does not exist as, in some instances, the palpable appendix may be felt gradually diminishing in size until it regains the ribbon-like condition of the normal organ, while the patient is free from symptoms of disease. Neither is it correct to say that a chronic typhlitis or colitis is generally (or do some extremists say always?) due to the condition of the appendix and that it cannot recover till the appendix is removed. This statement is a reversal of the true order.

The dietetic treatment of chronic typhlitis consists in making the patient nearly a vegetarian. Beef, lamb, sweetbreads, chicken, comprise most of the available meats. Roasting and broiling are almost the only allowable modes of cooking. Preserved meats, fish, shellfish, and pork, are to be regarded with suspicion. Coarse vegetables, as cabbage, onions, carrots, sauerkraut, beans, corn, on account of its harsh seed-coats, greasy preparations of all kinds, excepting clean, sweet butter, cream and olive oil, are to be avoided. An excess of sugar may prove to be an irritant, although not directly concerned in the virulence of the colon bacillus. With a variety of breadstuffs, crackers, but not biscuits (in the American sense), nor pancakes nor other hot breakfast foods, with potatoes, sweet potatoes, pumpkin, squash, peas, green beans, tender lettuce, celery, asparagus tops and the many excellent cereal novelties now on the market, the patient need not suffer for lack of variety. For dessert, fruit free from seeds, skin and core, custards, gelatine puddings and cream dishes, may be allowed. Al-

coholic beverages, tea, coffee and strong chocolate must be avoided.

An important item in the treatment of typhlitis is to insure the proper condition of the intestinal contents. Therefore, the meals should be eaten at regular intervals, at least five hours apart, mastication should be thorough, the dentist's aid should be invoked if necessary and attention should be paid to any defect of gastric digestion.

While rest in bed is absolutely indicated, during the subacute attack, chronic cases require moderate exercise, if for no other reason, to maintain a proper motility of the bowels. In order to upset the stand-pipe constituted by the cecum and ascending colon, in which the intestinal contents have their longest delay while the water is being abstracted from them, it is well to advise the recumbent posture for short intervals several times a day. Heavy lifting, and excessive strain or fatigue of any kind should be interdicted. It should be borne in mind that the greatest benefit of exercise consists in fresh air and rest, not in muscular development. As a rough rule, the patient should be advised not to walk more than three or four miles daily nor to wheel more than ten or twelve, but, in the latter exercise grade, road-bed and direction of wind are more to be considered than distance.

Tonic medication naturally suggests itself. The theoretic objection to arsenic has already been stated. Iron should be used, if needed—and not unless the need is actually demonstrated—only in the mildest forms, such as the saccharated carbonate, the organic imitations of hemoglobin, the vegetable salts, the freshly-prepared albuminate made by mixing the chloride with milk or egg-water. Perhaps the very best preparation is the hemoglobin of rare meat. Bitter tonics are of little use under any circumstances. Strychnine may be used p. r. n.

As a means of direct treatment of the cecum, oil suggests itself as forming a protective dressing. Vegetable and animal oils, although advocated for this purpose, are objectionable as they are changed into soap and glycerin in the bowel and as any excess not thus digested is a stimulant of peristalsis. The ideal emollient—although used internally, it is not a demulcent—is a pure mineral oil which passes the entire length of the alimentary canal without change, which is aseptic if not antiseptic and which is bland and harmless. Odorous volatile impurities should be rigorously excluded and only the denser, lubricating hydrocarbons should be present. Color, save the faintest suggestion of opalescence in reflected light and taste—beyond the peculiar smooth feeling which the patient is apt to call a taste—are evidences of impurity. Pure mineral oil acts as a mechanical laxative without causing irritation either in its direct action on the mucous membrane or by unduly stimulating peristalsis.

As an astringent and protective for internal use, we have practically only one base—bismuth, although cerium is a fair substitute. While there are a number of more or less synthetic bismuth preparations on the market, and while many of these are excellent in the treatment of the small intestine, the need of care in avoiding too active astringents in treating the cecum and the desirability of keeping separate, drugs intended for different purposes, so that the astringent, protective and antiseptic actions may be severally increased or decreased as indicated, has led me to abandon the newer bismuth salts for the carbonate. Partly as an antiseptic, partly for its action in promoting better local blood supply, partly because of its antispasmodic effect—in the true, local sense—menthol is indicated in the majority of cases. The following formula may be used:

℞ Bismuthi subcarb..... 30.0 (℥ i)
Menthol..... 3.0 (gr. xlv)
Pure petroleum.....450.0 (℥ iv)
S. Fifteen c.c. (tablespoonful) midway between meals and at bed-time.

In this prescription the menthol is in solution, in the mineral oil, the bismuth merely in emulsion so that a shake label is necessary. The time of administration is selected so as to interfere as little as possible with gastric digestion and lavage practised on patients who have had some concomitant gastric catarrh has shown that the emulsion is rapidly passed through the pylorus so that it does not appear in the wash-water, five hours after a meal. In any particular case it is impossible to prophesy just how far the laxative tendency of the oil, the constipating tendency of the bismuth and the state of the patient's bowels will balance. Sometimes it is necessary to reduce the bismuth or to discontinue it altogether for a time. Sometimes the oil must be stopped. Sometimes a genuine cathartic, like effervescent sodium phosphate, must be given.

Treatment should be maintained quite actively for two or three months, unless after a subacute attack with no previous trouble and promptly taken in hand. If, after five or six months, the patient remains well, is able to endure gradually increasing physical exertion and to relax the diet somewhat without evil consequences and if, most important of all, the appendix remains free from tenderness and is impalpable or ribbon-like, the case can be considered cured. With increasing age, the tendency to typhlitis and appendicitis, as to typhoid fever, diminishes on account of the decadence of lymphoid tissue in the bowel. With this exception, however, it is doubtful whether a patient is ever so thoroughly cured by medical treatment that he is less susceptible to a recurrence of the disease than he was originally, when in a state of health, to the primary attack. The same limitation is applicable to most medical diseases, save those that are distinctly semelincident. Surgery has the advantage of removing the possibility of certain local diseases, including those of the appendix. But it is not possible to carry this plan to its logical limit without subjecting the body to mutilation worse than the danger of disease and while surgery may render appendi-

citis impossible, on the same principle that a blind man cannot be offended by horrible sights, it cannot well obviate the danger of typhlitis and it leaves the patient with a weakened abdominal wall.

THERAPEUTIC STUDIES OF HEROIN HYDROCHLORIDE.

By BENNO HYAMS, M.D.,
OF NEW YORK.

Of the many drugs recently brought to the attention of the general practitioner there is one, namely, heroin, which by virtue of its efficacy and therapeutic value bids fair to assume a permanent and prominent place in our pharmacopœia. This article concerns itself more properly with its salt, heroin hydrochloride, which, owing to its greater adaptability, is preferred in general use.

Heroin hydrochloride, a neutral salt of heroin, a new morphine derivative, is a white, odorless, crystalline powder of slightly bitter taste, freely soluble in water, acetic and dilute sulphuric acids. Its physiological action has been aptly and concisely described, as that of "a respiratory stimulant and a sedative to the respiratory mucous membrane." Its action in relieving cough and dyspnea is prompt; and its ready solubility renders it peculiarly suited for hypodermatic administration, especially where immediate results are required. It has little if any antipyretic properties; its action on the temperature is not marked, prominent or constant. In the majority of my cases I have noticed a slight reduction, but not sufficient to entitle it to practical consideration in this regard.

Respiration is profoundly influenced in all cases. There is a decided diminution in the frequency of the respiratory movements, with a prolongation of the inspiration and an increase of the force of expiration. The elimination of bronchial secretion is promoted, thus aiding in the relief of dyspnea. The pulse becomes slightly diminished in frequency and likewise somewhat fuller. It is in no sense a hypnotic, except that it indirectly relieves the distressing symptoms which prevent sleep. In therapeutic doses there is no disturbance of the gastric functions. Except for a slight nausea noticed in one case no ill-effects were observed. Its action on the intestine seemed to be a slightly constipating one. To overcome this it may be advantageously combined with cascara sagrada.

I have found the drug well borne in both the young and the old, especially so in the former. I consider this a point of special moment. As an anodyne in painful affections it ranks much below either morphine or codeine.

The after-effects which I have noticed have been a slight nausea in one case, dizziness in two cases, languidness in two cases, and a pharyngeal irritation, with constant desire to clear the throat. I may add that none of these sequelæ was of a serious nature and soon passed off without special treatment.

In cases marked by a diminution in the expectoration, the drug may with advantage be combined with either the iodide of potash, ipecac, terpin hydrate, or squill, in such ways as may suggest themselves in each individual case. As mentioned, in cases attended with constipation, the addition of cascara sagrada is effective.

The average dosage by mouth is from 1/24 to 1/6 grain, three times daily. It is preferably given after meals, especially when there is a diminution of gastric secretion, in which condition if dissolved in an acid medium and taken after the ingestion of food it fulfills all requirements. It may be given in powder, pill, tablet, or solution. It is freely soluble in acetic acid and dilute sulphuric acids, and although the former seems to be the solvent most frequently used, I have seen no advantage that it possesses over the latter. After the prolonged use of the drug, as in tuberculosis, larger doses are required. For prompt effect it is employed by hypodermatic injection for which its ready solubility in water renders it especially suitable. Four to eight minims of a two-per-cent. solution represent 1/12 to 1/6 grain, the smaller dose being the average amount necessary. The incompatibilities to its use internally are alkalies and apomorphine.

The following cases are among those in which I have tested the drug, both by mouth and by injection. The diseases treated comprised mostly respiratory troubles, in which cough and dyspnea were the most prominent symptoms. The results obtained were nearly all good, a few excellent, and two failures (diabetes). In bronchitis, especially in the acute variety, it is nearly specific.

Case I.—Mrs. L. N., aged thirty years, married. Family history markedly neurotic. Diagnosis: A nervous form of asthma of five years' duration. The patient is extremely nervous and suffers from frequent exacerbations, coming on irregularly and without known cause. Nasopharyngitis and bronchitis occasionally precede an attack. I was called in to see her for the first time during the last attack. The patient, a well-built woman, presented a typical picture of spasmodic asthma of rather a severe nature. She was sitting up in bed, using all the muscles of respiration to satisfy her air hunger. The dyspnea was most profound. The skin was livid, the face anxious, and the pulse feeble. Auscultation revealed sibilant and sonorous râles over both lungs caused by contraction of the bronchi. Examination was otherwise negative. I at once administered 1/12 grain heroin hydrochloride hypodermically and repeated this in ten minutes. The effect soon became apparent; the dyspnea became less and less; the circulation began to be restored, and in a very short time the patient presented a normal

appearance. For the distressing cough I prescribed the following:

℞ Heroin hydrochloride...0.20 (gr. iij)
Extr. belladonnæ.....0.06 (gr. j)
Pulv. ipecacuanhæ.....0.20 (gr. iij)
Extr. gentianæ.....q. s.

M. ft. tabl. No. xxxvi. Sig., one tablet every two hours.

After three days the cough was greatly improved and in a week had entirely disappeared. No unfavorable effect followed the hypodermatic injection.

Case II.—Mr. R. S., aged sixty years. Diagnosis: Chronic bronchitis. Patient at present complains of dyspnea, pain in the chest, headache, and cough. Temperature 101.8° F.; pulse 100. The most prominent symptom is a wheezing in the upper part of the chest. I administered heroin hydrochloride, 1/12 grain by hypodermatic injection, and continued this dose by mouth three times daily after meals dissolved in dilute sulphuric acid. The injection gave immediate relief and, although the symptoms still persisted, the cough was much relieved and the dyspnea less severe. The patient informs me that for all previous attacks large doses of morphine were necessary to alleviate the distressing symptoms, and that while he was promptly relieved he suffered from the after-effects of the medication. He earnestly assures me that he has experienced none of these under the heroin treatment.

Case III.—Miss E. K., aged nineteen years. Family history negative. Diagnosis: Acute miliary tuberculosis. (?) The prominent symptoms are cough with profuse mucopurulent expectoration, pain in the chest, afternoon fever, night sweats, and general weakness. Beside antituberculous treatment she was put on heroin hydrochloride, 1/12 grain, every two and one-half hours, dissolved in acetic acid. The distressing symptoms were at once checked, and in three days she was greatly improved. The patient has since passed out of observation. I may state that after using the heroin for a few days I substituted codeine, and have found the alternation of heroin and codeine an effective one in some cases.

Case IV.—Mrs. F. H., aged fifty-five years. Diagnosis: Angina pectoris. During the attack I administered hypodermatically heroin hydrochloride, 1/8 grain, in alteration with nitroglycerin. Between the attacks she received iodide of potash. The attacks, which at first were as frequent as eight a day, gradually grew less frequent in number, duration, and severity. As the condition improved the dose was diminished, and the drug finally stopped. Except for a slight nausea no ill-effects were observed.

Case V.—Miss A. B., aged seventeen years. Diagnosis: Acute bronchitis. The principal symptom is an irritable cough. I prescribed heroin hydrochloride, 1/12 grain, and also the iodide of potash, 3 grains, every three hours, and an additional dose before retiring. At the end of six days the cough was under control.

Case VI.—A. S., aged twelve years. Diagnosis: Acute bronchitis. The chief symptoms are pain on inspiration and cough. He received tablets of heroin hydrochloride, 1/12 grain, three times daily after meals. This dose not being large enough, it was increased to 1/12 grain, every two hours. As a result the boy began to mend quickly, and the cough soon disappeared.

Case VII.—W. G., aged four years. Diagnosis: Malaria, scrofula, and chronic bronchitis. In addition to antimalarial and tonic treatment he received heroin hydrochloride, 1/36 grain, three times daily. The symptoms were soon under control.

Case VIII.—Mr. W. B., aged twenty-seven years. Diagnosis: Acute bronchitis. Cough with diminished expectoration was present. He received heroin hydrochloride, 1/8 grain, with iodide of potash, 5 grains, three times daily. Alleviation of the symptoms occurred in a few days.

Case IX.—Mr. D. L., aged thirty-three years, weight 122 pounds. Diagnosis: Pulmonary tuberculosis. Duration of disease three years. The patient complains of severe pain in the right chest, a hard, persistent cough worse at night, diminished expectoration, night-sweats, insomnia, slight shortness of breath, fever, and general malaise. Examination of the sputum shows a moderate number of tubercle bacilli. Percussion reveals marked dulness over the upper portion of the right lung anteriorly. There is also increased voice and vocal fremitus; fine moist râles are heard over the area of dulness. The heart shows the lesions of mitral stenosis. Among other treatment he was given heroin hydrochloride, 1/6 grain, three times daily, in combination with iodide of potash, 5 grains. In three days the cough was less marked and the expectoration became more abundant. On the seventh day the cough had nearly disappeared, and that night for the first time in a long while he slept uninterruptedly. The night-sweats and dyspnea had disappeared. This case shows the very great value of heroin in cases of pulmonary tuberculosis. Not only is its action in relieving the cough and the dyspnea noteworthy, but also its action in causing a disappearance of the night-sweats; and above all, notwithstanding the presence of a well-marked cardiac lesion, relatively large doses were used without any apparent dangerous after-effects.

Case X.—J. S., aged five years. Diagnosis: Whooping-cough. He was given a prescription containing heroin hydrochloride, dilute sulphuric acid, and tincture of belladonna. The case has not been sufficiently long under observation for absolute deductions to be made, but it appears to me that this combination is very effective in checking the number and the duration of the paroxysms, and, while not curative, allows the disease to run a mild course.

Case XI.—Miss A. L., aged nineteen years. Diagnosis: Acute bronchitis. Hacking cough, profuse expectoration tinged with blood, dyspnea, pain in the chest. Temperature 102° F., pulse 100. I prescribed heroin hydrochloride, ipecac and phenacetin. The symptoms at once improved, and in ten days the cough was gone.

Case XII.—Mrs. J. B., aged fifty-three years. Diagnosis: Chronic bronchitis, with coexisting nasopharyngitis. Expectoration scanty, dyspnea, cough, general weakness. Heroin hydrochloride, 1/6 grain, three times daily, was administered. In a week the patient was much improved and the cough was nearly gone.

Case XIII.—Mrs. H. B., aged forty-five years. Diagnosis: Diabetes mellitus of eight years' standing, with complicating nephritis, and gangrene of one of the toes of the left foot. Among other treatment she received heroin hydrochloride, 1/6 grain, three times daily. No good results were noticed.

Case XIV.—Mrs. B. R., aged fifty-nine years. Diagnosis: Diabetes mellitus of about fifteen years' duration. No complications. She was placed upon a proper diet and given codeine without any benefit. Heroin hydrochloride was then substituted with the same result. The drug seemed to have absolutely no effect on the progress of the disease. It seems to me, as far as my limited experience with the treatment of this disease by means of heroin is concerned, that it is of the same doubtful efficacy as codeine, etc., and all the remedies which have been landed as curative of this condition.

To sum up briefly: Heroin hydrochloride is indicated in coughs of all kinds, whatsoever the cause, in dyspnea and in all catarrhal inflammations of the respiratory mucous membrane, and in all cases in which morphine is contraindicated. In acute bronchitis the combination of heroin hydrochloride with ipecac seems to be particularly effective. In chronic bronchitis and in asthmatic conditions the addition of the iodide of potash is of much value. In whooping-cough, with belladonna, its action proved palliative. In diabetes my results have been poor. In pulmonary tuberculosis, I regard this drug as one of the best remedies with which to combat the cough, dyspnea and night-sweats. A drug which can be used for long periods without dangerous sequelæ, and at the same time exerts the effect before mentioned, is peculiarly suited to the treatment of this often protracted disease.

A NEW OPERATION FOR HEMORRHOIDS.

By ELLSWORTH ELIOT, Jr., M.D.,
OF NEW YORK;
SURGEON TO THE PRESBYTERIAN HOSPITAL AND INSTRUCTOR AND CLINICAL LECTURER IN SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

There is scarcely any condition in which the surgeon can assure relief by operation with as great certainty and with as little risk as in that of hemorrhoids, in spite of the impossibility, due to the prevalent local uncleanliness of the bowel, of carrying out strict antiseptic precautions.

The factor which is probably most responsible for this usually favorable termination is the dilatation of the sphincter which accompanies each operative procedure. This has long been recognized as an efficacious method of treatment in all

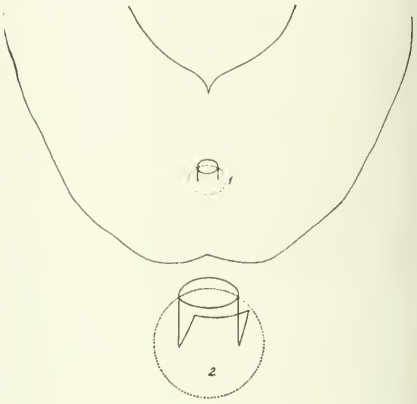

Fig. A. (1) Preliminary Incision. (2) Incision magnified, heavy lines represent cut surfaces.

those cases of hemorrhoids in which the development of the pathological procedure is such as to demand a radical operation for its relief. It acts by providing a greater freedom of anastomosis between the portal and systemic radicals, which, in the ordinary case, is frequently hampered by the contraction of that muscle resulting from a more or less inflamed condition, if not actual ulceration, of the mucous membrane of the lower part of the bowel. This same procedure is also of the greatest advantage in that it provides absolute rest and thereby favors the healing of any granulating surface after operation, eliminating the danger of protracted and obstinate ulceration. Stretching of the sphincter also favors the rapid healing of the operative field, and this is greatly to be desired in that the danger of cicatricial contraction after a protracted course of healing by granulation is prevented.

Stretching of the sphincter does not, however, always secure the rapid and complete healing described. Occasionally a condition of obstinate and protracted ulceration complicates convalescence and requires a longer interval of rest, afforded by the complete division of the sphincter, before healing can be secured. Such an unfortunate termination is at times followed by the development of stenosis requiring the occasional passage of a bougie to ensure the patency of the anal orifice. This accident may follow any one of the operations for hemorrhoids. In a case, recently observed, it followed an Allingham

operation, where the removal of the hemorrhoids resulted in a considerable sacrifice of the overlying mucous membrane. It occasionally develops after a Whitehead operation, where a ring of cicatricial tissue has resulted after a more or less protracted course of healing, from the retraction or sloughing of the sutured mucous membrane. After the procedure by the clamp and cautery, the healing by granulation of the denuded portions of the mucous membrane may give rise to similar trouble.

The possibility of this complication after the usual operations for hemorrhoids induced the writer to devise some means whereby prompt healing might be secured and the danger of stricture reduced to a minimum, without impairing the serviceability of the operation.

The following procedure, which has been tried during the past six months in the Presbyterian Hospital, of this city, has given excellent results in a number of cases:

After the customary preparation and with the usual precaution of as perfect cleanliness as is possible under the circumstances, an anesthetic is administered, and, the sphincter having been stretched, the hemorrhoids are allowed to protrude. Each advanced hemorrhoidal area is treated similarly as follows: Opposite the base of the hemorrhoid, parallel with and corresponding to the mucocutaneous junction, a curved incision is made and carried upward in the same plane as in a Whitehead operation beneath the pile-bearing area until the base of the hemorrhoid is reached. A second curved incision is then made in and through the mucous membrane, forming an ellipse with the first-mentioned incision and including within this ellipse any area of ulceration at the base of the hemorrhoid that may have developed as a result of the irritation

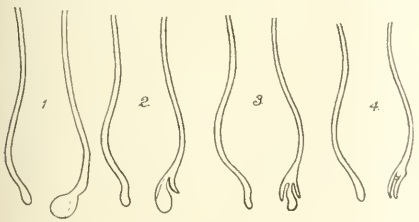

Fig. B. (1) Showing hemorrhoid, dotted line of first incision. (2) First incision completed, second incision, dotted line. (3) Second incision completed. (4) Hemorrhoid cut away, surfaces ready for suture.

to which the exposed surface of the mucous membrane overlying the hemorrhoid is subject.

From the junction of the two curved incisions, that is, from each pole of the ellipse, an incision is carried vertically upward through the mucous membrane only and the resulting quadrangular flap of mucous membrane is reflected from the surface of the underlying hemorrhoidal area, having its base of blood-supply superiorly. After the dissection of this flap of mucous membrane, the same vertical incision is deepened through the hemorrhoidal tissue proper, the resulting hemorrhage being slight owing to the direction of the incision, thus forming a rectangular mass of hemorrhoidal tissue which is transfixed at its base with stout catgut—if necessary with chromicized gut; the ligatures are then tied tightly and the hemorrhoidal mass removed. The rectangular flap of mucous membrane is then stitched to the skin, and the retention of any discharge prevented by cutting the catgut ligature long and allowing the ends to protrude below between the sutures, thus acting as a drain. This same procedure is repeated in not more than two other places where the development of the hemorrhoids is most pronounced. At the conclusion of the operation, a dressing of sterile gauze is placed over the suture line, a large tube, surrounded by iodoform gauze having been previously introduced upward into the lumen of the gut to facilitate the exit of any gas or of accumulated fecal material.

By this method prompt union is usually secured, because the intervening portions of mucous membrane that have not been disturbed by the operation prevent the retraction of the flaps of mucous membrane that have been raised from the surface of the hemorrhoids. The situation of the suture line is also favorable to a prompt union, inasmuch as it is placed close to the anal ring and, therefore, is easily kept protected by the application of either sterilized or iodoform gauze. Sloughing of the flap of mucous membrane is very unlikely as the vascularity of the flap is most abundant and any pressure by the accumulation of the discharge is prevented by the drainage of strands of catgut which project below through the suture line. Should healing, however, take place by granulation, occurring throughout the entire field of operation, each resulting cicatrix would then be separated by a bridge of healthy mucous membrane which would effectively prevent the development of subsequent contraction and stenosis.

An objection may be raised to the effect that in those cases in which the entire circumference of the anal orifice is involved, a portion of the hemorrhoidal area is not removed by this operation. This objection obtains in only the most advanced cases, as after this procedure the intervening portion of hemorrhoidal tissue rapidly shrinks, for the reason that it has been subjected to the benefit of the stretching of the sphincter, and that its condition of venous engorgement is materially lessened by the division and ligation of those vessels supplying the hemorrhoidal area removed.

Another advantage of this procedure consists in the fact that it permits of the complete excision of all areas of ulceration at the base of the hemorrhoids and thereby lessens the possibility of subsequent infection, necessarily favoring, at the same time, prompt union of the divided parts.

A PLEA FOR THE EARLIER RECOGNITION OF SQUINT IN CHILDREN BY THE FAMILY PHYSICIAN AND THE EARLIER APPLICATION OF THE METHODS OF TREATMENT.[1]

By C. A. VEASEY, M.D.,
OF PHILADELPHIA;

DEMONSTRATOR OF OPHTHALMOLOGY IN JEFFERSON MEDICAL COLLEGE; ASSISTANT ATTENDING OPHTHALMIC SURGEON TO JEFFERSON MEDICAL COLLEGE HOSPITAL, ETC.

It is a well-known fact that a large proportion of the cases of squint met with in ophthalmic practice begin in childhood. The period of most frequent occurrence is that age when the little one begins to make accommodative effort, as in looking at pictures, picking up blocks, etc., usually at about the age of four or five years. Some cases are, of course, congenital; others the acquired within the first few weeks of life and others still are paralytic and may appear at any time; but the greater number become manifest about the time mentioned.

The family physician, as a rule, has his attention directed to the condition shortly after its appearance. If he is indifferent and says (as I have known to be done frequently), "Oh, the child will outgrow it, let it alone," in most cases the squint will become permanent and a portion of the visual acuity of one eye may be lost. On the contrary, if the proper treatment be instituted much can be done toward relieving the deformity and at the same time preserving the useful vision of both eyes, as well as in avoiding the many neurotic ailments to which eye-strain frequently gives rise.

It is not within the province of this paper to review the different causes of squint. It might perhaps be well to add, however, that it is not caused by looking at a lock of hair falling to one side of the face, by fright, by imitation of another cross-eyed person, or, as suggested to me by the mother of one of my patients, by "eating a dish of cold beans purloined from the kitchen pantry."

The larger number of cases, as previously intimated, depend upon some disturbance between the relation of accommodation and convergence, a condition generally brought about by some error of refraction. It would seem, therefore, that the proper procedure in all cases of squint, excepting, perhaps, those of paralytic origin, would be to determine whether there is present any error of refraction. If one is familiar with the use of the ophthalmoscope this can be readily done; if not, one drop of a solution of atropine, four grains to the ounce, should be instilled into each eye night and morning and the child's eyes protected from strong light; in fact, dark glasses should be worn out-of-doors if the child is old enough to keep them on. Should the squint disappear, or become very much better, it will prove that an error of refraction is present in the case, the strain upon the accommodation having been relieved by the action of the atropine upon the ciliary muscle, and the patient should be carefully glassed. Should the patient be too young to wear glasses, the atropine instillations, in half strength, may be kept up at varying intervals in the meantime in order that the excessive accommodative efforts may be relieved. The youngest patient for whom glasses were prescribed by the writer was three years of age, a case of convergent squint with Jacksonian epilepsy, in which the squint disappeared and the number of convulsions was markedly reduced. Frequently littles ones from three and one-half to five years of age have worn glasses and complete correction of their squint has resulted in a comparatively short period of time.

If the wearing of glasses for several weeks fails to correct the defect a system of muscle gymnastics known as "orthoptic exercises" should be employed. The apparatus required is an ordinary box stereoscope with a series of double pictures. The patient is first taught to recognize both pictures on the cards, or to see double, thus showing that both eyes are used at the same time, and after this has been accomplished to fuse the two pictures into one. This method is of very little use in cases of high degrees of squint in which the glasses produce but little change; but in cases of low degree, or in cases much benefited by the wearing of glasses, or in cases of residual squint after operation, it is decidedly of the greatest value.

Should the wearing of the proper glasses and the faithful systematic employment of orthoptic exercises fail to cure the squint, recourse must be had to operative measures. This usually consists of a tenotomy of one muscle or an advancement of its opponent, or both, depending upon the amount of deviation to be dealt with, the variety of the squint, the strength of the opposing muscle, and the condition of the visual acuity of each eye. If the defect is convergent the eyes should not be entirely straightened at the operation, but a small amount of residual squint should be permitted to remain, as there is always a slight after-tendency to divergence.

For the same reason in operating for divergent squint it is better to produce a very slight convergence.

As to the age of the patient, it is best to wait until the child is about six years old, though there are a few cases in which earlier operation seems advisable.

These few brief notes give but a meager outline as to the methods to be followed in the treatment of concomitant convergent squint and are offered principally to direct the attention of the family physician to the condition upon its first appearance, so that it will not be put aside as something to be outgrown, but will receive the prompt attention it deserves.

THE TREATMENT OF PNEUMONIA WITH ANTI-PNEUMOCOCCIC SERUM.[1]

By EDWIN ROSENTHAL, M.D.,
OF PHILADELPHIA.

THE bacterial origin of disease brings as a natural sequence the study of its prevention and cure. In the province of therapeutics the most surprising and positive results have been shown, and medicine has passed from what was always termed the "expectant" method of treating disease to what may now be termed the "positive or specific" method.

The history of these discoveries is too new to be mentioned and it would be a waste of time—in a ten-minute paper—to even quote from them. It is taken for granted that the knowledge of the etiology of pneumonia is so well known that to take up the subject of its treatment with pneumonic serum needs no introduction into its cause, pathology or course. One point, however, must always be conspicuously borne in mind, and that is the clinical history of each case; in applying the remedy one should always know whether the disease is a primary croupous pneumonia or a secondary catarrhal pneumonia. The history of each case varies and no treatment can be termed specific, but the nearest approach to this can truly be claimed for the serum treatment. In the type of the disease one can see its indication and in a measure control the result; with the knowledge of its incubating signs one can prevent, or, if that be impossible, abort, and when it is too late to prevent or abort, one can, in a measure, curtail its duration, or if the disease is met at its height, its course can be directed to a favorable termination.

Clinically, pneumonia is met with as croupous pneumonia, a self-limited disease which should end favorably, and catarrhal pneumonia which has no limitation. In this latter type, if there is a remedy that can not only cure the disease, but curtail its duration, such a remedy should receive most thorough investigation.

A very great and essential factor in all histories of catarrhal pneumonia is told in the word —complication. While croupous pneumonia may be a simple and single infection, that of catarrhal pneumonia is most complex, and disappointment in any method of treatment is due to the lack of knowledge as to what this complication may be. Most frequently catarrhal pneumonia is seen as a complication of measles, and it might be added that no disease is exempt. The knowledge of this fact should materially aid in its early recognition and treatment. Where pneumonia comes as a complication or sequel to other diseases, the antipneumococcic serum can be used at once, and the addition of the antistreptococcic serum is as needful, for in these instances pneumonia is most generally the result of streptococcic infection, and a case of this kind is the common history of mixed infection.

What is the remedy? Like diphtheria antitoxin and other medicaments of this class, antipneumococcic serum is obtained from the blood of other animals, notably the horse. The following is a brief outline of the methods employed in the production of antipneumococcic serum: A virulent culture of pneumococci is first secured and its virulence is greatly increased by being passed through rabbits. Instead of preparing bouillon, as for diphtheria and other antitoxins, the pneumococcus itself is grown directly upon glycerin agar. The live germs are employed in intravenous injections in the horse, differing from the production of diphtheria antitoxic serum and antitoxins generally, as usually it is the toxin which is injected and not the germ itself. On account of the virulence of the germs, it is first necessary to subject them to a temperature of 60° C. for one hour in order to destroy a portion of their activity. The dose is increased at each injection, the live germs, without heating or attenuation, being used in the later injections. The animal is treated for from three to four months before its blood is taken and the serum separated.

As in all serum treatment of diseases, the earlier it is used the more certain is the result, and if used early enough or at a favorable moment it so changes the course of the disease that the different stages close together; the process is curtailed or aborted, and from a state of high inflammation with all its symptoms of high temperature, quick pulse and respiration, comes a rapid crisis, the history of a favorable termination of croupous pneumonia, but brought about by the serum treatment within twelve to twenty-four hours instead of five to nine days, the time otherwise required.

The method of administering the serum is by hypodermic injection into the tissues of the body. I have chosen, in all instances, the sides of the chest, and even the affected side. After the parts are thoroughly cleansed with soap and water, and then with sublimated cotton or gauze, soaked in alcohol, the serum is injected by means of an antitoxin syringe, and the aperture is closed with iodoform collodion.

The indications for its use are as follows: The temperature, pulse and respiration should be taken as a guide, and the severity of these symptoms governs the method and size of dose and its repetition. If, for instance, the temperature be 103° F. or over, the pulse 140 or over, and the respiration 48 or over, I begin with 20 cc.; where the type is more severe, with 40 cc. of the serum, followed every four hours by double the initial injection, until the disease is under control, as manifested by a decline in temperature, a slower respiration, disappearance of pain, improvement in the pulse and a change for the better in the general condition.

If the case be croupous in character, this

[1] Read before the State Medical Society of Pennsylvania, Wilkes-Barre, Sept. 18, 1900.

method alone is sufficient and the first twenty-four hours or perhaps forty-eight hours show the effect of the remedy. Where, however, pneumonia is secondary to another disease, the antipneumococcic serum alone is not sufficient. Therefore, the injection of antipneumococcic serum should be followed in four hours by one of antistreptococcic serum.

The use of the serum does not in any way interfere with any other treatment, nor is it harmful in any quantity at any stage of the disease. At the same time suitable remedies should be employed and the method pursued with which one is most familiar. As an example, wet packs and the use of digitalis, whiskey, ammonium carbonate, strychnine and the like, may be persisted in, and indeed any indication which the exigency of the case may demand can be applied without regard to the use of the serum. If the serum be used and additional medication be pursued, the results from such medication may not only be satisfactory but quickened, showing the specific action. When used early, that is, before the inflammation has become so marked as to pass the stage of resolution, the antipneumococcic serum has no influence in curtailing the progress of the disease, and the antistreptococcic serum may be necessary to prevent the results ensuing.

A most pertinent rule must be appended to be followed by those who are not familiar with the commercial history of the serum. None of the foreign antipneumococcic serums or antistreptococcic serums are reliable, since they are too old when they reach the practitioner in this country, it being well known that these serums do not retain their action beyond three months, under the most favorable conditions.

One must always remember that it is not the one dose nor the one bottle that will cure, but sufficient quantities must be used until results are obtained, whether this is done with one dose of 20 cc. or with twenty bottles of the remedy.

CLINICAL MEMORANDA.

SEPTIC SYNOVITIS OF KNEE-JOINT: EXTENSIVE DRAINAGE FOLLOWED BY EXCISION OF ENTIRE SYNOVIAL MEMBRANE: RECOVERY.

By CHARLES A. POWERS, M.D.,
OF DENVER, COLORADO.

On Tuesday, September 27, 1898, I was asked by Dr. J. D. Nye, to see B. S., a girl of thirteen years who gave the following history: She had always been well with the exception of scarlet fever in December, 1897, from which a complete recovery had been made. She had never had difficulty in walking, she had had no trouble whatever with either of the lower extremities. In May, 1898, she fell several feet from a stand which collapsed in the City Park, but she sustained no immediate inconvenience and suffered no difficulty in locomotion as a consequence.

On Tuesday, September 20, 1898, she was in her usual health and rode a bicycle in the evening. On Wednesday, September 21st, she was suddenly seized with severe pain in the right knee. There was some swelling of the joint. She remained in bed and was seen in the evening by Dr. Nye, who found her with a temperature of 104° F. and a pulse of 100. The right knee was moderately swollen and exquisitely tender and painful. The usual local and general measures were employed but the joint continued to swell. The temperature during the succeeding week ranged between 101° F. and 103° F., the pulse running from 100 to 120 per minute.

She was first seen by me, as said, on Tuesday, September 27th, just one week after the onset. At this time the mouth temperature was 102.5° F.; the pulse 120; the right knee-joint was much swollen, exceedingly tender and painful. The patient had been receiving a fair amount of morphine; she was very restless and nervous.

A diagnosis of suppurative synovitis was made, drainage advised and at once carried out under ether at St. Luke's Hospital. An exploring needle passed into the joint at its outer aspect withdrew pus. Incision of the joint was made at the outer side, beneath the patella, another incision at the inner side of the joint, and a third incision above at the upper margin of the synovial pouch. These incisions were according to the ordinary method of Hueter. The joint was thoroughly washed, evacuating shreddy fragments of pus and broken-down tissue. Large tubes were inserted, draining the joint beneath the patella in triangular fashion. The temperature and pulse did not come down after this irrigation and drainage, but remained high. The dressing was changed under chloroform at the end of forty-eight hours. The wounds looked rather sloughy, there seemed no further purulent secretion in the joint, but thick broken-down tissue was evacuated. Six hours later the temperature was 104° F.; the pulse 126 and feeble. The patient seemed desperately ill, there was marked albuminuria, the lips were dry, the face was anxious.

Further operation was advised and the knee-joint was opened by the usual curved incision, under ether, at 9 P.M., September 29th. The entire synovial membrane was dark greyish in color, much thickened, septic and semigangrenous in appearance; the lower end of the femur and the upper end of the tibia seemed free from disease. The entire synovial membrane was carefully trimmed out, together with a liberal layer of adjacent tissue; the semilunar cartilages and crucial ligaments were removed. The entire upper recess of the synovial pouch was cut away and marked attention was paid to the posterior aspect of the joint, the tibia being well dislocated forward. The patella was removed.

After thorough irrigation the flap was lightly tacked below and the cavity well packed with iodoform gauze and plain sterile gauze; a large dressing was applied. At the close of the operation, which occupied thirty-five minutes, the pulse was 150 and very feeble. A large saline infusion was given, the extremities bandaged and elevated and the patient was vigorously stimulated with strychnine, atropine, coffee and whiskey.

Her condition on the following morning was fairly good, the pulse was 130; the temperature 102° F. The knee-joint was free from pain for the first time since the invasion of the disease. The dressing was changed under chloroform every three or four days for some four or five weeks. The subsequent course was slow, but uneventful. At the end of three months the entire wound was solidly healed, the limb being ankylosed in a position a trifle flexed. I am unable to account for the septic invasion of this girl's knee-joint. There was no evidence of wound or scratch on any part of the extremity. It seems hardly possible that it could follow at such a remote day upon the scarlet fever of the previous year. Unfortunately a bacteriological examination of the pus was not made at the time of operation.

It is needless to say that septic inflammation of the knee-joint is a condition of the greatest possible gravity. Many cases will recover under simple drainage and irrigation of the joint, the synovial cavity being divided into several pouches or parts for drainage. Hartley has devised a method of draining the joint posteriorly and an excellent suggestion is that of Mayo of Rochester, Minnesota, who makes a transverse incision at the front of the joint, saws the patella in two, partially dislocates the tibia forward and in this way is able to reach and pack with gauze all portions of the synovial cavity. After granulation is established he sutures the sawn surfaces of the patella, and in two cases out of four has been able to obtain one-fourth range of normal motion.

I can report on but three personal cases in addition to the foregoing. One of these, a very recent case, was in a man of forty-five years who accidentally thrust the point of a pair of scissors into the lower part of the knee-joint. I saw him with his attending physician on the fifth day. At that time his temperature was 102° F., his pulse about 90. He had been delirious from the first day. His knee-joint was much swollen, very tender and painful. Exploration showed it to contain pus. It was very thoroughly drained after the method of Hueter, but his condition did not tend to improve. It was at no time such as to warrant either excision or amputation. He continued in marked delirium and died of progressive sepsis two weeks after operation. My other two cases recovered, one with a stiff joint and the other with about one-fifth range of motion.

THE INFLUENCE OF MEASLES AND ERYSIPELAS UPON EPILEPSY, WITH REPORT OF CASES.

By L. PIERCE CLARK, M.D.,
of Sonyea, N. Y.;
First Assistant Physician, Craig Colony for Epileptics,
and
E. A. SHARP, M.D.,
of Sonyea, N. Y.,
Medical Interne.

Evidence of a negative character, or that which goes to positively disprove an existing theory, is usually not especially desired by many investigators of disease. But in the analysis of an existing theory one must necessarily weigh negative as well as positive evidence in order that a working hypothesis may be obtained which shall be true and not misleading. This is noteworthy in considering the influence of infectious and febrile disorders upon a preexisting epilepsy.

The subject is an old one, even dating from the time of Hippocrates, who noticed that a preexistent epilepsy or mental disorder was frequently favorably modified by an acute traumatic or febrile process. Since that time many investigators have written upon this subject. Of late the general opinion seems to be that an infectious process in the course of a chronic nervous or mental disease is advantageous and should be encouraged to the point of establishing such an element for curative purposes. This has especially been advocated during the past two or three years by some French and Italian writers, who have urged the establishment of malaria in epileptics and, when the epilepsy is recovered from, the cure of the malaria by the exhibition of quinine.

In our experience of several years with epileptics, we have known but two cases in which the epilepsy was notably bettered by an intercurrent disease, while, on the contrary, we have seen many epileptics in whom the disease has been made much worse by such accidents or complications. Now and then we still see a report of an improvement of a neurosis under some accidental complication. Experience of this kind is fairly common to the neurologist. The idea has been quite contagious, and even the general public is imbued with it. In consequence many people believe that insanity and the degenerative neuroses, such as epilepsy and idiocy, may be permanently cured by contracting erysipelas, pneumonia or chronic malaria.

With the idea of presenting some testimony in regard to this subject, we wish to report in abstract some cases that have suffered from epilepsy for variable periods of time and with varying degrees of severity, during the course of which measles and erysipelas have occurred. The notes and comments upon these cases are as follows:

Cases of Measles.

Case I.—J. S., girl, six years of age; epilepsy of grand-mal type since two years of age, which resulted from an infantile cerebral palsy. She

contracted measles March 28, 1900. The incubation period was unknown; patient undoubtedly became contagioned at her home prior to being admitted to the Colony, as the symptoms made their appearance a few days after admission. On third day rash appeared on the face, forehead, and neck, and on the following day the rash appeared over the entire body. The blotches were irregular, reddish and crescentric; the face was swollen; the rash disappeared on pressure; it persisted four days; the eruption was that of German measles. Temperature was 103.2° F. at onset; within twenty-four hours the temperature had become nearly normal, but the rash persisted as noted before. The pulse was 130 at onset, ranging from 145 to 96 during the five days. Desquamation was slight—fine scales over the flexor aspect of the extremities. Patient had no complications except a slight laryngitis; there were no sequelæ. Treatment was by isolation, confinement to bed, liquid diet, tepid sponging, enemata, diuretics, camphorated oil and vaseline. Recovery was complete in eleven days from onset.

Patient had no convulsions during the attack of measles; she had suffered from two severe convulsions for the same period of time prior to the onset of measles. For an equal period after, patient had no attacks; but now, some five months after, the attacks are once more frequent and severe. While the measles appear to have temporarily stopped the epileptic attacks, no permanent good resulted from the same.

Case II.—E. S., girl, six years of age, epilepsy began at seven months of age and is of grand-mal idiopathic type. Patient contracted measles April 15, 1900. The period of incubation was about ten days. The infection began with slight fever and coryza. The symptoms were all mild and the patient was not very ill. The rash began on the first day, slightly on the face, and spread over entire body in twenty-four hours. It was fully developed in thirty-six hours. The rash was irregular, reddish, crescentric in outline and places and disappeared on pressure. On the third day the rash began to fade, and entirely disappeared by the fifth. The temperature was 99° F. at onset and never reached over 100° F. It was normal after the third day, at which time the rash began to fade. The pulse ranged between 80 to 92 throughout. The desquamation was so slight as to be scarcely perceptible. There were no complications or sequelæ. The treatment was by isolation, confinement to bed most of the time, liquid diet, enemata, camphorated oil and vaseline. Recovery was complete in nine days.

During the attack of measles the patient had no convulsions; she had had no convulsions for an equal period before the measles. For an equal period after, no attacks presented themselves; but since then, for the past three months, convulsions have been as frequent as before. In so far as the patient had no attacks for an equal period prior to the onset of the measles, as well as none for an equal period after, it is difficult to tell just what influence the measles had upon the preexistent epilepsy; but certainly it has not materially modified the course of the neurosis.

Case III.—F. S., girl, six years of age, epilepsy began at three months of age. Patient contracted measles April 18, 1900; the period of incubation was about thirteen days, patient being exposed before the complete recovery of Case I. The temperature at the onset was 100.8° F.; coryza, redness of eyes, running at nose, slight cough, which became more severe during the next two days, were present. The eruption began on the second day, with small red papules on the face and forehead, and became larger, irregular, blotchy or mottled, and crescentric in outline on the third day. On the fourth day the eruption had spread over the entire body; on the fifth it began to fade and entirely disappeared on the seventh day. The temperature reached the maximum of 104° F. on the third day. It ended in crisis the fourth day. The pulse was irregular at the start, ranging from 95 to 140. Its ranges were not parallel with the fever-curve. Desquamation of fine bran-like scales was complete in three days. There were no complications or sequelæ. The treatment was by isolation, confinement to bed, liquid diet, diuretics, enemata, tepid sponging, camphorated oil and vaseline. Recovery was complete in ten days.

On April 19th, at the time of maximum of temperature, patient had one severe attack at 11:00 P. M.; another at 1:00 P. M., and still another at 3:20 P. M., all of which were of grand-mal type. The three attacks all occurred on the second day of illness, before the rash became well marked. Patient had no convulsions for an equal period prior to the onset of the measles, and had none for the same length of time after; but six weeks after, having passed that time in apparent immunity from seizures, the attacks of grand mal appeared again, and during one month patient had more attacks than for any previous month.

We see in this case no permanent immunity or improvement after having had measles, but on the contrary the disease was made worse.

Case IV.—L. D., girl, fourteen years of age; epilepsy began at one year of age. The epilepsy was apparently of the idiopathic grand-mal type. The patient contracted measles April 22, 1900, the period of incubation being about fourteen days. She was exposed to Case I. at the same time as the other cases. The invasion began with cough and coryza and the temperature rose rapidly at the onset. The patient was weak and seemed to suffer severely from the disease. The eruption came out on the second day and spread quickly over the entire body, but was less pronounced in character than in other cases. On the fourth day the rash became more distinct, but it still was not well pronounced. The rash was irregular, reddish blotches, while the skin was cyanotic between the rash spots. The peripheral circulation was extremely poor from

the start; in fact, patient had been subject to areas of asphyxia and cyanosis in attacks (previously commented upon by French writers as accompanying certain forms of epileptic attacks). The skin was cold and clammy throughout the measles. The temperature began at 100.6° F. and increased to 105° F. on the third day, continuing high, with slight remission for a few hours at a time, until death on the sixth day. Respiration and pulse increased from the start; the pulse-rate was very feeble throughout and ranged to 160. Patient had suffered from pulmonary tuberculosis for some time and died of status epilepticus. The treatment was by isolation, confinement to bed, liquid diet, cardiac stimulation, morphine and potassium bromide during status, and hot baths. Patient died in status epilepticus April 27th, complicated by extended pneumonic consolidation from previous tuberculous process. Autopsy proved the tuberculous and pneumonic lesion and a congenital narrowing of the aortic orifice was found, to which the condition of peripheral cyanosis and asphyxia was attributed, as other writers have previously held.

On April 24th, two days after the onset of the measles, patient had one severe grand-mal convulsion at 3:00 P. M. On April 27th she had seven more severe attacks in rapid succession, which terminated in typical status epilepticus. She had had no epileptic attacks for an equal period prior to the onset of the measles. In this case it seemed that the condition of measles was directly provocative of status epilepticus. While we are aware that this is uncommon, Bourneville and Noir have reported similar cases.

Case V.—E. R., girl, seventeen years of age; epileptic attacks of idiopathic grand-mal type. The epilepsy began at one year of age. Patient contracted measles April 22, 1900. The period of incubation was about fourteen days. She was exposed to Case I. at the same time as the others. The invasion began with a slight cough and coryza. Fever and general symptoms of measles advanced daily in step-like manner. The eruption began on the first day with small red papules on the face, spreading over the entire body on the second day. They were blotchy, irregular and crescentric. The rash did not entirely disappear until the ninth day. The fever began with 102.6° F. at the onset of measles and increased to 103.6° in a few hours. There was a gradual decline to normal on the fifth day, ending by crisis. The pulse ranged from 85 to 100. Desquamation of fine scales, scarcely perceptible, occurred for one week after convalescence. Laryngitis existed as a complication, but there were no sequelæ. The treatment was by isolation, confinement to bed, liquid diet, sponging, enemata, diuretics, camphorated oil and vaseline. Recovery was complete in twelve days from the onset

For an equal period prior to the onset of the measles, patient had had twenty or thirty severe attacks each month. For an equal period thereafter, patient had one severe attack, but since then the attacks have been as frequent and severe as before. The lessened number of attacks lasted for two months only.

Cases of Erysipelas.

Case I.—M. H., girl, aged twenty-seven years, epilepsy of idiopathic grand-mal type; she had been epileptic since ten years of age. Patient had a severe attack of facial erysipelas from April 11 to 24, 1900, which was accompanied by mania. She had one petit-mal attack at the time of the erysipelas, two grand-mal attacks at an equal period just before the erysipelas, and six grand-mal attacks for an equal period thereafter. In this case the erysipelas seems to have provoked a severer form of epilepsy.

Case II.—J. R., man, aged forty-two years; idiopathic grand-mal type of epilepsy; he has been an epileptic since ten years of age. Patient had severe attack of facial erysipelas from May 7 to 16, 1900. There were not any epileptic attacks during the complication of erysipelas. He had but one attack for an equal period of time before and none for an equal period thereafter. Since this attack of erysipelas, and during the last two months especially, the epileptic convulsions are as before the infectious process. The problematical improvement, which might have been ascribed to the erysipelas, did not remain permanent.

Case III.—C. W., man, aged fifty-five years; his epilepsy began at forty-four years of age, caused by alcoholism. The convulsions are of grand-mal type. Patient had a mild attack of facial erysipelas from April 14 to 18, 1900. During this period patient had no epileptic convulsions, neither had he any attacks for an equal period before or after; but since this time attacks of epilepsy have occurred in their regular course as in the past few years.

Case IV.—J. W., man, aged forty-six years; his epilepsy began at eighteen years of age and is hereditary; it is grand-mal in type. Patient had severe facial erysipelas from April 14 to 25, 1900 which extended into the right arm and shoulder, during which time he was continuously delirious. There were no epileptic attacks during this interval and none occurred for an equal period prior to this time, while three occurred for an equal period thereafter.

Case V.—C. B., man, aged thirty-two years; his epilepsy is of the idiopathic grand-mal type; he has had epilepsy since sixteen years of age. Patient had a severe attack of facial erysipelas from April 19 to 26, 1900, during which time he had six grand-mal attacks and was constantly maniacal; for an equal period prior to this thirteen attacks occurred. For an equal period of time after the erysipelas, patient had three attacks. Soon thereafter attacks became more persistent and severe, and patient died from status epilepticus one month later.

Case VI.—M. C., woman, aged twenty-five

years; her epilepsy began at seventeen years of age, at which time the disease was supposed to have been provoked by an attack of erysipelas. Patient's attacks have always been infrequent, occurring once in four or five months. Facial erysipelas of a severe type occurred June 24, 1899, and lasted until July 26th, during which time no convulsions occurred and the course of the epilepsy did not appear modified. Since this time the patient has had cellulitis of the deep tissues of the neck, without modifying the course of the epilepsy.

Case VII.—A. B., man, aged thirty-seven years; he has had epileptic attacks since sixteen years of age; the epilepsy is of the idiopathic grand-mal type. Patient had severe facial erysipelas from March 7 to 14, 1900, during which time no epileptic attacks occurred. One grand-mal attack occurred for an equal period of time prior to this and two grand-mal attacks appeared within an equal period of time thereafter. Since then the attacks have occurred at regular periods, four or five times a month.

Two additional cases have come under our notice, details of which we have not at hand, but in neither was the epilepsy permanently benefited.

Our deductions from the study of these cases are that *in not one instance was the preexisting epilepsy favorably modified for any great length of time.* In a few cases the progress of the disease was accelerated by the infectious complication, and *in one the measles caused status epilepticus.* In those cases in which the epilepsy was favorably modified, the temporary improvement was slight and of very short duration. We are therefore forced to the conclusion that instead of the physician urging his patient to run the risk of an infectious disease, with the small chances of such an accident resulting favorably to the existing neurosis, he should urge them to avoid any and all such complications as far as possible.

MEDICAL PROGRESS.

Vaginal Hysterectomy.—G. Bouilly (*La Gynecologie*, Oct., 1900) reports a case of death after this operation due to peritonitis infected by loops of the intestine protruding through the wide-open vaginal vault into that canal. This accident led him to adopt the following modification: The last step of the operation is to draw the lips of the vaginal wound down and suture them together in the median line. Through the small openings on each side of this suture the vascular stumps with the clamps are gently everted. In this way the peritoneum is absolutely shut off from the vagina and its packing.

Ablations of the Trigeminal Ganglion.—Julius Dollinger (*Centralbl. f. Chir.*, Nov. 3, 1900) modifies the Krause-Hartley operation by planning the bone flap so as to avoid the lower front corner of the parietal bone and in it the anterior branch of the middle meningeal artery. Next he finds the main vessel within the cranial cavity and, working away from it forward and inward, finds the second and third offsets from the ganglion. Thus ligating or accidental division of the vessel is avoided and simplicity and brevity in operating attained.

Feeding in Typhoid Fever.—The effects of a more generous diet in the treatment of typhoid fever than is the usual practice to give are discussed by George W. Moorehouse (*Boston Med. and Surg. Jour.*, Nov. 15, 1900) in a study of a series of 150 cases of which he reports 117. The average time the patients were kept on a milk diet was ten days. As soon as the appetite began to return to any patient soft typhoid diet was at once ordered without direct reference to the temperature. The appetite and not the temperature was the guide to the continuance and increase of the diet once begun. The typhoid diets adopted by the writer are: (1) Milk diet, eight ounces every two hours, subject to special directions as to night feedings; (2) liquid typhoid diet, consisting of milk, milk with tea or coffee, albumin-water, beef-tea, malted milk, chicken-broth and barley-water, beef-juice and barley-water; broths, milk whey, junket, strained soups or gruels may also be given; (3) soft typhoid diet, to be added to the milk or liquid diet, (*a*) ice cream, well cooked (boiled) rice, broths thickened with it; (*b*) soft boiled or poached egg on soft toast, blanc-mange and milk puddings, calf's foot and other gelatin jellies; (*c*) gruels, crackers or bread softened in milk or broths, macaroni, finely-minced or scraped meats; the increase in diet to be very gradual, one addition only each day; (4) typhoid convalescent diet, to be added to anything above, the soft parts of oysters, a sweetbread, chop, cutlet, squab, game (small), chicken, fish, steak, rare roast beef; a mealy baked potato may also be given with any of the meats; (5) full typhoid diet, 6 A. M., milk; 8 A. M., a cereal with cream and a little sugar, milk with tea or coffee, egg on toast, bread or toast with butter; 10 A. M., bread and butter, with gruel or milk, or broth with egg; 11:30 A. M., soup, meat or fish (anything mentioned above), ice cream, blanc-mange, or milk pudding; 2 to 3 P. M., like 10 A. M.; 4 to 4:30 P. M., creamed chicken, or a bit of cold chicken or roast beef, bread, and milk flavored with tea or coffee; 6 P. M., cocoa, gruel or broth; at night, milk two to four times. Any change from a less to a more generous diet should always be gradual. The mortality in the 150 cases, thus fed, was 8.67 per cent. There were relapse-like rises of temperature in 30 of the 117 cases. In nine cases this relapse occurred before, and in 21 after, a more generous diet was begun. The writer believes this high proportion (18 per cent.) of relapses to be due to the fact that he has doubtless included among the cases of relapse many which would not be so classified by

others. The temperature charts show very clearly that the increased feeding does not interrupt the defervescence. The important features in these diet lists are (1) the articles permitted, and (2) the directions for the increase in diet, insuring the gradualness of any increase from a less to a more generous diet level. The new level was reached in the average case in about four or five days. Moorehouse says that patients fed generously begin to put on flesh at once, and show a continuous gain in strength and spirits as well as in flesh. He thinks that liberal feeding is a distinct advantage as regards prompt recovery of normal condition.

Iodine Used Hypodermatically in Pulmonary Tuberculosis.—After noting the fact that essentially the same tissues are affected by iodine as by the tubercle virus A. C. Croftan (*Jour. Am. Med. Assoc.*, Nov. 17, 1900) reports 27 cases of incipient pulmonary tuberculosis which he has treated by hypodermatic injections of iodine. Nineteen of these were cases of incipient tuberculosis with only circumscribed areas of infection, while in eight cases larger areas in one or both lungs were involved. A ten-per-cent. solution of iodipin was the iodine preparation used. Beginning with one drop of iodipin in one-half dram or so of sterilized oil, each day the dose of iodipin injected was increased by one drop until improvement was apparent. Much depended on the personal idiosyncrasy of the patient and the stage of the disease. There were never any bad effects of any sort from these injections of iodipin. More than sixty minims a day have not been injected. The results were uniformly beneficial. The appetite improved, the cough and night-sweats became less severe, and the patients gained in weight and improved in spirits. The physical signs were modified and seemed to show that the process was at least being held in abeyance and rendered latent. The writer does not consider the results obtained so far conclusive, as the number of cases is as yet small and they have not been observed sufficiently long, but he does think that the results warrant an optimistic view of the efficacy of this method of treatment.

Pseudopest Cases.—Dr. Arthur Mendonca (*Revista Medica de Sao Paulo*, Brazil, Sept. 15, 1900) presents some notes on certain cases of disease that were suspected to be pest during the recent epidemic and as such were isolated for a time. During the epidemic any patient suffering from adenitis was liable to suspicion as a case of the bubonic plague. Some of these cases prove rather difficult of differentiation. The bacteriological test was the final criterion. In a dozen of cases the buboes proved to be due to nothing more serious than staphylococcus aureus. One very suspicious case proved on direct examination to have no germs of any kind in the pus obtained from the swollen glands. Cultures on agar gave rise after twenty-four hours to colonies that looked very much like those of the typhoid bacillus. Under the microscope a bacillus was found that resembled the bacillus of pest. When followed through various culture media, however, the bacillus presented many characteristics very different to those of the pest bacillus and the conclusion was that the patient was not suffering from the much-dreaded disease. At the isolation hospital one very suspicious case occurred in an Arab. The direct examination of the pus from the inguinal swelling did not reveal the presence of any germs. In the cultures a pseudodiphtheritic bacillus was found in pure culture. This was taken to preclude the idea of pest. A bacillus very similar to that found in the case of the Arab was found in the pus from a supraclavicular lymphatic swelling in a woman under examination at the Hospital of the Strangers. It is evident that this bacillus would be the source of considerable difficulty in suspected pest cases. In a third case, in which no germ could be found on direct examination, the pest bacillus was found in the cultures, and along with it a sarcina. Whether this had any influence in producing a state of affairs in the serosanguinolent fluid of the bubo that concealed the presence of the pest bacillus is left open to conjecture.

Modern Quarantine.—The term "commerce destroyer" has been applied to coast quarantine with considerable justice, according to the belief of A. H. Doty (*Med. Rec.*, Nov. 3, 1900). The wholesale destruction of large cargoes from infected ports has been undoubtedly unnecessary in many instances. From his long experience as health officer of the port of New York, the author believes that the clothing actually worn by well persons is not a medium of infection, and he is equally certain that a ship's cargo seldom, if ever, is the cause of transmission of infectious disease from one port to another. He contends, however, that the mild or ambulant cases of infectious disease and convalescents from these diseases constitute a serious menace to public health and are chiefly responsible for the outbreaks which occur from time to time. It follows, therefore, that more attention is paid to the condition of passengers and a rigid inspection is made to determine whether any are affected. If the incubation period of the disease which is suspected has not elapsed, the ship is detained in Quarantine, and to avoid the possibility of the presence of mild or latent cases the clinical thermometer is made use of and found very reliable. At the end of the incubation period, although there may not be any symptoms present, a slight temperature is an almost constant sign, and any person reaching 100° F. is detained long enough to determine the cause of the rise. It is believed that the public is thus given the full protection and commerce is relieved of unnecessary delay and expense, a most important consideration.

Abdominal Suture.—In order to prevent ventral hernia through laparotomy cicatrices, such

as are the common experience of all surgeons, says Gottschalk (*Archiv f. Gynaekol.*, Bd. 61, Hft. 2), complicated methods have been proposed. The chief point to be observed is proper apposition of the various layers, each to each, throughout the wound. During the past six years he has satisfactorily made two rows of sutures only. The first takes in everything from the peritoneum to the aponeurosis of the external oblique, each inclusive, and the second secures the subcutaneous fascia and the skin. As the individual sutures of the deep series are tied the assistant apposes the layers. The skin stitches dip into the aponeurosis in order to prevent pockets. As to incisions, it seems to make no difference whether the central or lateral avenues are taken. The various cross incisions in the sheath of the rectus appear to favor hernia.

Incineration vs. Earth Sinks.—Since it is the history of all wars, with the exception of the Franco-Prussian war, that preventable diseases have caused more deaths than the bullet, the disinfection and disposal of the offal from camps becomes an exceedingly important subject for investigation. The use of zinc-lined troughs containing milk of lime has hitherto been generally accepted as the most convenient method, but it has been proven to be very ineffectual in preventing the spread of a contagious disease, especially typhoid fever. W. G. Bissell (*Med. Rec.*, Nov. 3, 1900) has been investigating the subject most thoroughly and experiments have been made during the last two New York State encampments. Incinerators have now been constructed by the State and found efficient by several regiments at the last encampment. There are eight incinerators placed on a suitably covered and ventilated wagon. Each incinerator is so constructed that the excrement is received into a pot beneath which is a fire-box, and the draught so arranged that all the odor from the pot is drawn down into the fire-box, the indol, skatol, etc., being thoroughly converted and oxidized and then allowed to escape by a chimney at the top. Besides being found very convenient, incineration is far more efficient for the final disposal of excrement, is less objectionable as regards labor, odor, etc., and with greater certainty eliminates the opportunities for camp pollution, rendering the spread of typhoid fever almost impossible. The recent Spanish-American war showed that in spite of the great advancement made in bacteriological methods, camp sanitation was markedly lax, and it is to be hoped that radical improvements will be at once made.

Alcohol in Pneumonia.—In discussing the diet in the acute stage of pneumonia, A. H. Smith (*International Med. Mag.*, Oct., 1900) says that it is now accepted that alcohol is a food as well as a stimulant, and as such it may be employed to replace in part, or to supplement, other diet in the acute stage of pneumonia. He thinks that it can be used with advantage much earlier in the disease than it is usually administered. Its distinctly antigermic property aids in inhibiting the local bacterial activity as is shown by much clinical evidence. Many cases have been reported which have been saved when *in extremis* by the use of 20 to 30 ounces of brandy or whiskey in twenty-four hours. The writer says that alcohol may be used tentatively at any stage of pneumonia, and that its action will be shown to be beneficial if the pulse becomes less frequent and of greater volume, and the respiration slower and deeper, twenty minutes after the dose is taken. The amount and frequency of the dose should be regulated by the duration of the improvement in the pulse and respiration. In drunkards alcoholic stimulation begins only when the amount given exceeds the habitual allowance in health. The excessive mortality of pneumonia in heavy drinkers is probably due to the fact that the depression caused by the disease has added to it the prostration caused by a withdrawal of the amount of alcohol which has become a necessity to their existence. Therefore, an alcoholic with pneumonia should get his full daily allowance of spirits, after which the amount of stimulation may be considered. A pneumonia patient should be allowed to drink all the water he desires. The diet, of such a nature that it will not readily ferment, should be restricted to an amount that can be easily digested and assimilated. Flatulence should be prevented by modifications in the quantity and quality of the food. If other forms of food are not properly digested and assimilated the substitution of a greater proportion of alcohol is indicated.

Sterilization of the Hands.—A very effectual means of treating the hands before operation is described by J. Hahn (*Centralbl. f. Chir.*, Oct. 6, 1900) as follows: In running sterile water at about 40° C. with common yellow soap and sterile nailbrushes, the hands and forearms are scrubbed hard and systematically in four sittings of a few minutes each. After the second scrubbing the nails are cleansed and trimmed. Next there comes for four minutes immersion in a one-to-one-thousand solution of bichlorid of mercury in ninety-five per cent. alcohol, followed by washing in a one-to-one-thousand or one-to two-thousand watery solution of the same, until the alcohol is washed off. Finally, after the gown is put on, a rapid rinsing in the alcoholic solution is done, which may be followed by a superficial drying with a sterile towel, or, better, the hand may be left moist and the operation begun.

Chronic Copper-Poisoning. — The enormous growth of copper industries in this country has made copper-poisoning a much more frequent and important condition for treatment. H. A. Kurth (*Med. Rec.*, Nov. 10, 1900) has met with a number of cases connected with the Edison Electric Works. The brass-workers are the men

usually affected, especially the finishers and polishers. The copper enters the system both by the alimentary and the respiratory tracts. This causes by its irritant action a marked bronchitis, frequently becoming purulent, the formation of connective tissue around the bronchi, and therefore an excellent nidus results for the deposition of streptococci, tubercle bacilli, etc. The symptoms of greatest value in the recognition of copper-poisoning are, (1) dyspepsia, which is the earliest of all symptoms; (2) anemia, which comes on before emaciation, loss of strength and the rather characteristic painful facial expression; (3) nervousness and irritability. The prognosis is good when organic changes have not occurred and a change of occupation can be effected. The important part of treatment is prophylaxis. Iodide of potassium is generally useless. There is no specific drug, but strychnine in large doses is valuable and phosphoric acid has been strongly advocated by some writers.

Clinical Aspects of Gout.—The variety of clinical pictures which gout and rheumatism may present is considered by Beverley Robinson (*Med. Rec.*, Nov. 10, 1900), who believes that they are the cause of various obscure conditions. He is convinced that no absolute dietary rules can be laid down in the treatment of these diseases. He believes that gouty manifestations may appear in the prostate, uterus, ovaries and rarely in the intestines, and recently has advanced the theory that many cases of appendicitis are of a gouty or rheumatic origin. The recurring cases of appendicitis, especially in adults, which are now operated upon during the interval, should first undergo a thorough antirheumatic preliminary treatment for a sufficient length of time to justify the operatory intervention. He acknowledges that these cases are very difficult to differentiate, but insists that by medical treatment the dangers of an operation may frequently be avoided.

Recurrent Laryngeal Paralysis.—J. F. Culp (*N. Y. Med. Jour.*, Nov. 3, 1900) reports a case of sudden paralysis in a healthy man of the left vocal cord while the patient was smoking and conversing with some friends. No signs could be found leading to the suspicion of any pressure upon the nerve and a diagnosis of probable neuritis of the recurrent laryngeal nerve was made. Tobacco was interdicted. The throat was sprayed frequently with benzoinal and menthol. Tincture of nux vomica (fifteen minims) was given three times per day and the constant current of electricity was applied to the side of the neck. The patient made a gradual recovery, and at the end of six months there was a complete restitution of the functions of the larynx.

A New Test-Meal.—The test-meal has become absolutely necessary in examining the stomach contents. The three meals chiefly employed are Ewald's, consisting of one to two rolls and two glasses of water; Riegel's, consisting of soup, a beefsteak and a roll; and Klemperer's, consisting of half a liter of milk and two rolls. Ewald's meal is withdrawn one hour, Riegel's three to four hours, and Klemperer's two hours after eating. A. E. Austin (*Boston Med. Surg. Jour.*, Nov. 8, 1900) finds two serious objections to all of these meals, as follows: (1) The indefiniteness of the amount of the food elements employed, nitrogen, fat and carbohydrate, and (2) that on account of the lack of fine division the tube introduced is frequently clogged, which necessitates its removal, its cleansing and reintroduction. The writer has made a number of experiments with a test-meal consisting of two grams of dried egg albumin compressed into half-gram tablets, and two glasses of water, the contents of the stomach being withdrawn one hour after eating. The amount of albumin in these tablets is equivalent to that found in the rolls, or crackers, of the Ewald meal, but is in a different and more soluble form. The advantages of this test-meal of albumin tablets are: (1) The contents never clog the tube; (2) there is always a definite amount taken; (3) the contents filter much more readily than when vegetable albumin is used; (4) a large mass of starch granules is avoided; (5) these tablets when once compressed can be kept indefinitely, are always on hand and can be given to the patient without his leaving the office; (6) furthermore, lactic acid when found is of vastly more diagnostic importance than after the Ewald meal, because in this case the acid must come from the remnants of the last meal, and hence point to a lack of motility. The writer cites in detail a number of cases in which this meal was used, and discusses the results obtained, showing the advantages of the albumin tablets over other test-meals.

Phimosis.—G. Marion (*Semaine Médicale*, Oct. 24, 1900) adds to the usual steps of this operation an elongation of the frenum. It consists of a transverse incision parallel with the corona, in length to correspond to the degree of lengthening desired. When sutured the incision is converted into a suture-line in the long axis of the organ, thereby gaining its own length at the frenum.

Salpingitis.—M. Mironov (*Semaine Médicale*, Oct. 24, 1900) says many of the dangers of the stumps of the Fallopian tubes may be avoided by anastomosing them with the vagina in the following manner: Through an incision in the anterior vault the base of the bladder is freed from the anterior face of the uterus, the vesico-uterine leaf of peritoneum is incised and its anterior flap sutured to the front margin of the vaginal wound, shutting out the bladder from much likelihood of damage. The uterus is then drawn down into the wound and the tubes ligated at each cornu. If the ovary is diseased, that adnexum is totally ablated. If the ovary is

sound, it is left by separating it from the tube. The incision must be sutured over and over with catgut, to avoid raw edges. Then the tube is removed and the stump drawn down to and sutured along the vaginal wound, hence securing drainage into that canal. The opposite side is treated in the same way. The cul-de-sac of Douglas needs to be opened only when adhesions are too extensive to be handled otherwise.

Tuberculous Phlebitis.—Lesné and Ravaut (*Semaine Médicale,* Oct. 10, 1900) conclude that certain tuberculous processes may have a secondary involvement of the veins, but there are cases where the bacillus of Koch lodges primarily in the endothelium and there sets up either a typical lesion or one closely analogous to ordinary phlebitis. They have performed numerous experiments and find they can recover the germ for the guinea-pig test very satisfactorily.

Perineal Floor.—The influence of a relaxed or ruptured perineum on the vagina, bladder and rectum is well known, states D. de Ott (*Semaine Médicale,* Oct. 10, 1900), but their effect on the static and functional conditions of the abdominal organs is too little appreciated. Recently he had a patient, forty-five years old, with a ruptured perineum, suffering from consequent prolapse of the rectum and various pronounced constitutional disturbances, as emaciation, insomnia, etc. In addition there was a small polypus, situated high up, cherry-size, and attached by a long, slender, though tough pedicle. Its characters would hardly account for the disturbance so well as the rupture of the perineal floor. Consequently a careful restoration of the floor was accomplished, followed at once by disappearance of all local and systemic symptoms.

Treatment of Constipation.—According to E. Roos (*Münch. med. Woch.,* Oct. 23, 1900) one factor constantly overlooked in the treatment of constipation is the part played by the normal intestinal flora, in producing free movements. Accordingly, the author obtained the coli bacillus from feces, grew it on agar and filled the culture in gelatin capsules which were covered with collodion and keratine, each capsule containing one platinum loopful of the pure culture. Five such doses were given to several patients during five days with the result that they were relieved from constipation for the following two weeks. Experiments with dead bacilli proved negative. The bacillus acidi lactici, employed in a similar manner, caused increased peristaltic action and flatulence, but hardly relieved constipation. The addition of sugar to the diet did not increase the action. The author then experimented with yeast which has already been successfully employed in scurvy and furunculosis. Half a gram two or three times daily in keratinized capsules produced no gastric disturbances or flatulence, but on the second day or later the desired cathartic action. Dried yeast exposed to heat seemed to have an even more beneficial action.

Diphtheria Bacilli in Healthy Throats.—From a study of the throat cultures of 285 healthy individuals, 7 of which showed the presence of diphtheria bacilli, and of 190 healthy boys whose throat cultures showed the presence of the Klebs-Löffler bacilli in only 16, Francis P. Denny (*Boston Med. and Surg. Jour.,* Nov. 22, 1900) has drawn the following conclusions: (1) Diphtheria bacilli are seldom found in the throats of those who have not been exposed to diphtheria. (2) The bacilli are more frequently found in those who have been exposed, especially in persons living under poor hygienic conditions or in institutions. (3) The conditions of institution life which favor the growth of the bacilli in healthy throats are the living together of a large number of persons in a limited air space. (4) Healthy individuals with virulent bacilli in their throats can spread the disease. They are just as dangerous as mild or convalescent cases of diphtheria, and ought, therefore, to be detected and isolated. (5) Cultures ought to be made among those who have been exposed to diphtheria; (*a*) by physicians among the members of a family who have been exposed; (*b*) by inspectors in the schools; (*c*) by the health officers under any circumstances when they think the disease is being or may be spread by such individuals.

Tabes and Diabetes.—So many symptoms are common to both tabes and diabetes that even with positive signs it may be doubtful for some time whether one is dealing with the transient glycosuria of the nervous disorder or with a diabetes in which the neurotic symptoms are most prominent. Yet, according to W. Croner (*Zeitschrift f. klin. Med.,* Vol. 41, Nos. 1-4) both diseases rarely occur together. Among symptoms characteristic of both may be mentioned irregular areas of anesthesia or analgesia, paresthesiæ, especially about the legs and sexual organs, increased sensitiveness toward cold, lancinating pains, diminished sexual vigor, and trophic and secretory disturbances, such as malum perforans pedis, decubitus, hyperidrosis and muscular atrophy. Even Westphal's sign may occur in diabetes, but is of no prognostic importance. In those few cases, however, where both diseases really occur together, it may reasonably be asked whether this is accidental or whether some common etiological factor exists. The rarity speaks for coincidence, yet diabetes and tabes have been seen in different members of the same family and diabetes has occurred after injury to the cord. Diabetes insipidus may occur with tabes and it is admitted that the former not so seldom develops into diabetes mellitus. Finally, syphilis is looked upon by many as being capable of producing both disorders.

Creosotal in Lobar Pneumonia.—C. F. Stokes reports seven cases in which early defervescence followed the administration of creosotal, gram 0.7 (mxij), in capsule every two hours.—*Brooklyn Medical Journal.*

THERAPEUTIC HINTS.

Chalazion.—Strzeminski (Wilna) states that chalazion can be cured in two to ten weeks by nightly applications of this ointment:

℞ Iodi puri..... 0.2 (gr. iij)
Potassii iodidi..... 0.6 (gr. vj)
Lanolini..... 4.0 (ʒ j)
Petrolati liquidi.....
Aquæ destillatæ.....aa. 80.0 (ʒ iiss)

Cough in Phthisis.—A very effective mixture is:

℞ Codeinæ ..... 0.015 (gr. ¼)
Creosot..... 0.3 (ℳ v)
Syr. ferri iodidi..... 1.0 (ℳ xv)
Ext. malt..... 8.0 (ʒ ij)
Aquæ q. s.....ad. 15.0 (ʒ ss)

Tapeworm.—Make an infusion with grams 30.0 (ʒ j) of pumpkin seeds chopped finely and grams 240.0 (ʒ viij) of water, and to it add the following:

℞ Granati rad. cort..... 15.0 (ʒ iv)
Pulv. ergotæ..... 2.0 (ʒ ss)
Acaciæ ..... 8.0 (ʒ ij)
Ol. tiglii..... gtt. ij
Oleores. filicis..... 4.0 (ʒ j)

Emulsify the last two ingredients by means of the acacia. This makes one dose and it should be preceded by from twelve to twenty-four hours' starvation. If the head is not obtained repeat the dose in three days.

Bronchopneumonia.—The oiled silk jacket should be worn throughout the attack, says L. E. Holt, and counterirritation maintained by the use of mustard paste. Hot flaxseed poultices may be employed occasionally. Alcoholic stimulants are indispensable in severe cases; 15.0 to 60.0 ccm. (ʒ ss-ij) daily of whiskey or brandy for an infant of one year. If this is refused sherry or Tokay wine may be taken. Stimulants are most needed when the temperature is low, or falls suddenly. Strychnine, gram 0.0002 (gr. 1/300) every three hours, is valuable, and for heart failure nitroglycerin, gram 0.00012 (gr. 1/500) every hour for several doses. Atropine, gram 0.00008 (gr. 1/800), caffeine, gram 0.003 (gr.1/20), or strychnine, gram 0.0002 (gr. 1/300), may sustain through sudden failure of respiration, but their effect is only temporary. Oxygen is a good respiratory stimulant. Antipyretic drugs, quinine, expectorants, and emetics should not be used. For a temperature of 105° F., or when extreme nervous symptoms exist, bathe infants in cold water with friction, and apply the cold pack to older children. Cold is contraindicated and a hot mustard bath preferable when there is general cyanosis, cold surface, feeble pulse, shallow respiration and stupor. Inhalations have a general beneficial influence, relieve cough, and promote bronchial secretion. They are used by means of the croup-kettle or vaporizer, the child being under a tent. At first simply water-vapor or lime-water is used for ten to fifteen minutes four to twelve times a day; later turpentine, terebene, eucalyptol, and, especially, creosote may be added. Restlessness, loss of sleep, etc., are controlled by cold or tepid sponging, or phenacetine in small doses; Dover's powder, gram 0.015 (gr. ¼), may be needed to relieve pain or incessant cough. For a sudden attack of general collapse put the child into a hot mustard bath, use strychnine and nitroglycerin hypodermically, and give oxygen continuously. —*Diseases of Infancy and Childhood.*

Emphysema.—A valuable formula in use at St. Luke's Hospital is:

℞ Morph. sulph..... 0.005 (gr. 1/12)
Potass. iodid..... 0.3 (gr. v)
Tinct. belladon..... 0.65 (ℳ x)
Spt. ætheris comp....
Syr. pruni virg...aa. 4.0 (ʒ j)
Aquæ q. s.....ad 15.0 (ʒ ss)

Dose: One tablespoonful four times a day. This is often dispensed without the morphine.

Acute Intestinal Catarrh.—It is sound practice, says J. M. Anders, to prescribe a mild cathartic (castor oil, calomel, or rhubarb, followed by a saline), and to combine gastric lavage with high intestinal irrigation to overcome the fermentative processes in the alimentary tract. To control the inflammation, give the following:

℞ Salol ..... 2.0 (ʒ ss)
Creosot..... 0.65 (ℳ x)
Bismuthi salicyl..... 4.0 (ʒ j)
M. et ft. caps. No. XX. Sig. One every three hours.

If there is much pain opium or phenacetine may be added. In many cases the intestinal secretions are decreased, and such may require this:

℞ Pancreatin ..... 4.0 (ʒ j)
Sodii bicarb..... 8.0 (ʒ ij)
M. Div. in chart. No. XII. Sig. One an hour after meals.

If these methods do not control the diarrhea in forty-eight hours, give bismuth in two-gram (gr. xxx) dose every three or four hours, or pills of

Plumbi acetat..... 0.13 (gr. ij)
Ext. opii..... 0.008 (gr. ⅛)

If the main lesion is in the colon, small enemas of starch-water, grams 60.0 (ʒ ij), with laudanum, grams 1.3-2.0 (ℳ xx-xxx), every four to six hours, are efficacious. For thirst chipped ice, carbonated waters and Apollinaris; for distressing flatulence alkaline carbonates, spirit of ammonia, and some carminative, and for excessive fermentation oil of cajuput are recommended.

Glycerin for Erysipelas.—Duvergey and Bernex report two cases of facial erysipelas cured in about eight days with a brusque fall in temperature. They also record two cures of gangrenous erysipelas. Glycerin solutions are applied on compresses, injected into any infected body cavities, and used as a wash. In these cases the pulse became good, the temperature fell, the pain disappeared, and the bacteriologi-

cal test showed diminished virulence of the germs, and finally their disappearance.—*Journal de Médecine de Bordeaux.*

Incontinence of Urine.—Summing up the observations in 156 cases treated by *Rhus aromatica,* Perlis, in his thesis, states that this drug is equal, if not superior, to all the usual methods of treatment. The fluid extract is given in doses of 15 to 60 drops three times a day. Its mode of action is unknown, but it causes no unpleasant symptoms and the toxic dose is large.—*Le Mois Thérapeutique.*

Bed Sores in Spinal Disease.—As long as the skin is unbroken, the following dressing is recommended by J. H. Lloyd:

℞ Ol. ricini.....
Collodion .....aa. 30.0 (℥i)

If the skin is broken add to this a little iodoform. When sloughs have formed treat as any other severe open wound.—*American Textbook of Applied Therapeutics.*

Bathing in Rickets.—Baths which may be used with advantage in rickets, writes James Stewart, are: (1) Simple water for cleanliness, not below 90° F. for children under six months, with gentle friction, especially of the extremities, after the child is removed from the bath and dried. (2) Medicated baths with rock-salt, sea-salt, or, if anemic, iron sulphate in solution, given warm once or twice weekly. (3) Sun-baths and sand-baths at the seaside.—*Amer. Text-Book of Applied Therapeutics.*

Itching in Jaundice.—Gilman Thompson advises sponging the body with sodium bicarbonate, grams 12.0 (℥iij) in hot water, grams 500.0 (Oj), or applying McCall Anderson's dusting-powder of

℞ Camphor ..... 6.0 (℥iss)
Zinc Sulph. .....15.0 (℥ss)
Starch .....30.0 (℥j)

Anointing with cacao-butter may be of service.—*Practical Medicine.*

Catarrhal Jaundice.—Dabney recommends the following:

℞ Acid nitro-hydrochlor. dil. 23.0 (℥vj)
Tinct. nucis vom. ..... 15.0 (℥iv)
Tinct. gentianæ, q. s. ad.. 120.0 (℥iv)

Dose.—One teaspoonful three times a day in a wineglassful of water. For the nausea calomel in small doses, effervescing citrate of magnesia, lemon juice, ipecac, gram 0.016 (gr. ¼) every half to one hour, or chloroform water.

℞ Bismuthi subnitr. .. 0.13 (gr. ij)
Cerii oxalat. ..... 0.65 (gr. x)
Cocainæ hydrochlor. 0.0065 (gr. 1/10)

given with cracked ice, is especially valuable.—*Amer. Text-Book of Applied Therapeutics.*

Early Pulmonary Tuberculosis.—H. Carageorgiadès employs the following remedies: (1) *Cacodylate of sodium,* gram 1 (gr. xv), in syrup, grams 300.0 (℥x). Dose, a teaspoonful in water before each meal, increased gradually to two teaspoonfuls. This amount causes no stomach disturbance and strikingly increases the appetite and the weight, but after ten days' use, it should be omitted for the same length of time. It is painless hypodermically, and one or two injections of one cc. (♏xv) of the following may be given daily:

℞ Sodii cacodylat. ..... 0.50 (gr. viij)
Aq. destillata ..... 10.0 (℥iiss)
Formol ..... gtt. i

(2) *Ichthyol,* gram 0.25 (gr. iv), and *aristol,* gram 0.06 (gr. i), in pill, four to ten a day, increased to sixteen, and then reduced to ten or twelve a day. Ichthyol is better borne than creosote, and can be used in large doses for a long time. Aristol, being a combination of thymol and iodine, is a valuable adjuvant, and acts better than iodoform, which is often prescribed. (3) Cantharidine, gram 0.0001 (1/650 gr.), dosimetric granules, two to six a day. The researches of Buchner, Richet, and others, show that cantharidine induces an exudate of serum around a tubercular lesion; therefore if the serum is impregnated with medicaments, these will come into direct contact with the tubercle tissue. For this reason the author considers cantharidine indispensable in the treatment. Rarely it causes vesical tenesmus, but usually is taken for long periods without untoward effects. These drugs with plenty of fresh air, and superalimentation, including in the diet 6 to 12 yolks of egg and 100 grams (℥iijss) of cod-liver oil a day, constitute a most successful plan of treatment.—*Journal de Médecine de Paris.*

Vomiting as a Therapeutic Measure.—In inducing vomiting, writes Mitchell Bruce, we are not effecting a simple mechanical act of evacuation, but may at any time be alarmed to find intense circulatory depression, faintness, and even threatening dissolution. Before administration the patient's general condition must be carefully, if quickly, ascertained. In most cases of acute poisoning the patient can bear the shock and sulphate of zinc, gram 1.3 (gr. xx), in water, grams 60.0 (℥ij), sulphate of copper, gram 0.12 to 0.3 (gr. ii-v), in water, grams 30.0 (℥i), or a tablespoonful of mustard in a cupful of hot water, should be given at once. Where the products of croup or bronchitis block the respiratory passages, vinum ipecac, gram 4.0 (℥i) for children, or grams 15.0 (℥ss) for adults, is the best emetic, because it is also an expectorant. Antimony is decidedly depressing in dose of gram 0.06 to gram 0.12 (gr. i-ij) of tartarated antimony, or grams 15.0 (℥ss) of the wine, for an adult. Carbonate of ammonium, being a stimulant to heart and respiration, is suitable in these cases. In acute dyspepsia the mildest emetics are indicated, as tepid water, salt and water, and warm nauseous infusions such as chamomile; these may be freely given. Apomorphine is at once the most certain and generally applicable emetic in a dose of gram 0.004 (gr. 1/16) subcutaneously, or gram 0.008 (gr. 1/8) by mouth. It is frequently necessary to follow an emetic by a stimulant, such as alcohol.—*Materia Medica and Therapeutics.*

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, DECEMBER 1, 1900.

TYPHOID FEVER IN NEW YORK CITY.

So much has been said in the recent daily press about the prevalence of typhoid fever in New York City and its possible connection with the water supply that physicians are interested in definite authentic information as to the actual state of affairs. The Medical News has had some special investigations made and this may be considered as the position of the Board of Health on the question:

More cases of typhoid fever have been reported in the city during the present autumn than during the same season of last year. The typhoid fever incidence in 1899 was, however, lower than usual, and the number of cases that have occurred since September 1st of the present year is not greater than those reported during the same period in 1898, which was an average year. The decrease noted last year was probably due to better sanitary conditions. For the increase this year certain adventitious circumstances must be taken into account. The regulations as to the report of cases of typhoid fever are much better observed now by the physicians of Greater New York than they were last year. Outside of Manhattan there was a tendency to neglect reporting cases of typhoid which is now disappearing. In addition the introduction of the Widal test for typhoid fever has encouraged the reporting of cases of typhoid by making the diagnosis more assured. A certain number of doubtful and abortive cases of typhoid would fail to be reported under the older diagnostic methods.

The increase of cases of typhoid fever in the city is more apparent than real. The Widal test has been applied so much more extensively during the past year that this factor alone would probably account for most of the apparent increase.

It has been said that certain parts of the city are suffering much more than usual from typhoid fever. Harlem was designated by one newspaper as especially singled out by the disease. The Board of Health statistics do not support the statement, however. The present epidemic of typhoid fever, if epidemic it is to be called, is the usual autumnal visitation of the disease which in our large cities seems to be due to the fact that returning visitors from the country bring with them the germs of the disease and occasionally from them other members of the household become infected.

With regard to the city water supply as a source of the typhoid fever, the Board of Health considers that there is not the slightest reason to suppose any connection between the drinking-water and the development of the disease. Every case of typhoid fever is investigated for the purpose of determining its possible source and nothing has led the investigators even to suspect any causal influence in the water. If the drinking-water were at fault in this matter there would be many more cases of typhoid reported than there are at present.

COMPARATIVE FREEZING-POINT OF URINES.

Cryoscopy is a method of urinary examination that has attracted considerable attention on the Continent during these last two years. At the recent International Medical Congress at Paris an animated discussion as to its clinical value was shared by Frenchmen, Germans, Italians and Hungarians. The principle underlying the new method is that the freezing-point of solutions varies according to the amount and molecular composition of the substances held in solution. Raoult's law is "The lowering of the freezing-point of a solution is proportionate to the number of molecules dissolved in the unit of volume of water, whatever may be the nature and weight of the molecules." This law is considered so

absolutely true that its application is relied upon not infrequently in pure chemistry to furnish data for the determination of the molecular weights of chemical elements or compounds, the density of which in the state of vapor cannot be directly obtained.

Korányi of Budapest first suggested the employment of freezing as a clinical means of obtaining information with regard to the number of molecules in solution in urine. This number, of course, can only be determined comparatively. Of two urines the one having the lower freezing-point will contain, according to Raoult's law, the more molecules in solution. This fact, however, does not absolutely decide that it is the better excretory product. The sodium chloride of the urine is not an excrementitious substance, but one that has passed through the animal organism unchanged. Its function is physical, not chemical. The cryoscopic value of two urines can only be compared when their chloride contents are equal or when due allowances have been made for the influence of the chloride molecules on the reduction of the freezing-point of their respective urines. Normally there exists a definite ratio between the number of chloride-of-sodium molecules in the urine and the number of molecules of other substances in solution. This varies for different bodily conditions. When the value of the chloride factor increases without a corresponding increase in the value of other dissolved substances, the significance of the urine as an excretory product grows less and the patient is in a dangerous condition.

Korányi has shown that in cardiac cases careful observation of the cryoscopic value of the ratio between the chlorides and other substances in the urine enables the observer to anticipate the occurrence of cardiac failure. In renal affections the application of cryoscopy is even simpler. No matter what the form of the nephritis, according to Winter, the freezing-point of the urine is never as low as normal. As it approaches the freezing-point of water the danger for the patient becomes greater and greater. The urinary freezing-point has been known to be higher than that of blood-serum. At such a time, of course, if certain ideas as to the value of osmosis in urinary excretion are to be accepted, the value of urine as an excretory product is practically *nil*. When the freezing-point of the urine falls the prognosis in nephritis is favorable. In anemic conditions the freezing-point of the urine is higher than normal and one of the first positive signs of a change for the better in the blood condition comes when the freezing-point of the urine falls.

Bouchard of Paris approaches the subject of cryoscopy from a different standpoint. The freezing-point of the urine shows the number of molecules in solution. The number of molecules of organic material contained in urine depends on the elaboration of the albumin molecule in the animal system. The molecular weight of albumin is 6000; that of urea, its ultimate derivative in the human system, is 60, that is to say, 100 times less. Each molecule of albumin represents a large number of smaller molecules in the urine. The better the metabolism the greater will be the number of molecules in the urine. The freezing-point depends upon the number of molecules present, so that it can be considered within certain limits a criterion of the perfection of metabolism. In this estimation the chloride contents of the urine must also be taken into account, since chloride of sodium undergoes no modification in the body and its elimination is not the result of metabolic processes.

These cryoscopic methods are as yet rather theoretical than practical, although their application in hospital wards is not difficult. Whether the information to be obtained from them will ultimately prove of more clinical value than that which can be gleaned from the determination of the specific gravity and the estimation of the nitrogen of the urine, remains to be seen. The very general interest taken in the subject by European medical men shows that high hopes have been raised. Our present methods of urinary examination are confessedly crude and elementary. Cryoscopy seems to promise to throw some light on the comparative conditions of blood and urine at a given moment, and on the mysteries of metabolism and its variations. Let us hope that the expectancy of the medical world will not be disappointed.

THE BLOOD IN TYPHOID FEVER.

Scarcely another subject in medicine has been developed with the same giant strides to greater perfection than the study of hematology within recent years. The enthusiasm of a scientific generation has already well carried the subject beyond the realm of academic interest alone; its realizations in the field of practice have been many and more are forthcoming. Any new contribution to our knowledge of the blood is then especially

welcome at this time when medicine tends more and more to refinements of diagnostic methods. Perhaps no more interesting results of a study of the blood in typhoid fever have ever appeared than those recently made known by Dr. William Sydney Thayer (*Jour. of the Boston Society of Medical Sciences,* Oct. 16, 1900). This paper is based on an analysis of the examinations of the blood in the disease made in the Johns Hopkins Hospital during the last eleven years.

With regard to the quantitative and qualitative changes of the red blood-corpuscles practically nothing has been added to what was not already known by those engaged in this sort of work. As is well recognized during the first two weeks there are no considerable changes, apart from certain transient elevations in the count due to concentration of the blood brought about by diarrhea or sweating. Cabot states that baths have a similar effect. Contrary to the opinion of Hayem, who has always taught that the diminution begins rather suddenly in the middle or end of the third week of severe cases, Thayer finds, as does also Cabot, that the diminution in the number of the red cells becomes evident shortly after the onset of the typhoid fever and increases gradually throughout the course of the disease. Then anemia evidently bears a close relation to the severity of the disease; the average loss rarely exceeds 1,000,000 to the cubic millimeter. The loss of coloring matter in a general way parallels that of the reds.

The greatest value of the studies is really centered in the results of the white-cell counts under various conditions. All observers agree with Thayer's results showing a progressive diminution of the polymorphonuclear neutrophiles with a corresponding augmentation in the mononuclear forms. The limits of variation in the percentage of the polymorphonuclear neutrophiles is considerable; figures below 50 per cent. are not uncommon. These observations for the most part agree with those of Hayem, Khetagurow and Cabot. Among the lymphocytes the increase is not, as a rule, in the cells conforming to the type description, but in small forms with palely-staining nuclei, and a relatively large amount of transparent or nearly transparent protoplasm.

In cases with persistent fever there may be a tendency in the latter weeks of the disease toward a slight elevation of the leucocyte count, as compared with that at the height of the infection. However, unlike Aporti and Radaeli, the Johns Hopkins Hospital estimations show no tendency to a rise of the leucocyte count at the beginning of convalescence.

An increase to above 10,000 white cells to the cubic millimeter in typhoid fever is usually an indication of some foreign influence, such as cold baths, inflammatory complications, hemorrhages, etc. The transient leucocytosis which occurs after cold baths is very interesting; the increase may amount to three or four times the number before the bath. In this leucocytosis the relative proportions of the different varieties of colorless elements are unaffected.

Recognition of the fact that in uncomplicated cases of typhoid fever there is usually a condition of leucopenia is of the greatest importance, as will shortly be seen. Inflammatory complications, hemorrhage and perforation of the bowel are accompanied by a polymorphonuclear leucocytosis, the extent of which depends, apparently, more upon the nature of the local lesion than upon the species of micro-organism which may be the exciting factor. Cabot is, however, of the impression that when the cystitis or pneumonia is induced by Eberth's bacillus one is less likely to find a leucocytic increase. Leucocytosis is especially noticeable in connection with large abscesses, phlebitis, peritonitis, pleurisy, pneumonia, periostitis, cystitis and cholecystitis. It is worth remarking that the latter is doubtful. In some cases in which the complication is associated with a particularly malignant infection, Thayer rightly points out that the count of the leucocytes may not only fail to show an increase, but may even reveal a tendency toward a diminution in number, especially if the patient be already in a state of prostration. When hemorrhage from the bowel or perforation of the bowel occurs the count rapidly reaches above 10,000, although this is not invariable. The absence or disappearance of a leucocytosis following a perforation is an indication of the malignity of the infection or the prostration of the patient. The surgical features and indications of the leucocytosis in typhoid fever have already been the subject of discussion in these columns (*vide* Medical News, Oct. 20, 1900).

There are few diseases beyond the "diseases of the blood" in which hematological examinations may bring forward the same valuable information, not only with respect to the diagnosis of the typhoid fever itself, but about its complications, conditions in which the outcome of the treatment must often be measured by the time of making the diagnosis. Attention to the side

of blood diagnosis cannot be too strongly urged; all who become proficient in this will ever reap the richest reward.

ECHOES AND NEWS.

NEW YORK.

Much Scarlet Fever in Erie County.—Health Commissioner Wende of Buffalo reports an epidemic of scarlet fever at Williamsville. Thirty cases of the disease have been reported, and there are supposed to be several others.

Smallpox on the Upper West Side.—Last Tuesday six cases of children having smallpox were brought to the notice of the Health Department and all of them from the upper West Side. Four patients are colored, living in West Sixty-ninth Street, and the last in an apartment house in West Seventy-sixth Street.

Obituary.—Dr. Frederick Cornell De Mund died at his home, in Bensonhurst, on Tuesday last, in his seventy-first year. He was a graduate of Rutgers College in 1852 and of the College of Physicians and Surgeons of New York in 1855. He retired in 1895. He was at one time a School Commissioner in Kings County and Health Officer of New Utrecht. He leaves a widow, a son and a daughter.

Gift to Woman's Hospital.—At the forty-fifth annual meeting of the Woman's Hospital in the State of New York, which was held at the home of Mrs. Robert W. De Forest at 7 Washington Square, on Thursday, November 22d, President John E. Parsons announced that Mrs. Frederick F. Thompson, who recently resigned the office of treasurer, had offered to build a nurses' home in connection with the hospital, the home to cost between $100,000 and $150,000. The home will be built on the hospital grounds, which takes in the square block bounded by Forty-ninth and Fiftieth Streets and Park and Lexington Avenues. The latest gift of Mrs. Thompson is in addition to another of $55,000 which she made in the early part of the year.

Supremacy of the Law.—Michele Accette, physician, attended professionally Teresa Zupa of Brooklyn, and furnished her medicine, all to the value of $100; and she, in return, is showing the doctor why, in the interest of public health and sound law, he is not entitled to be paid (Accette vs. Zupa, 54 App. Div. 33). When he sued her for the amount, she set up that he was not "duly qualified, registered, and authorized to practise medicine as a physician in the County of Kings." The doctor proved that he was admitted to practice, and graduated from the University of Naples, had passed the examination of the University of the State of New York, had been licensed by the Regents of the University in 1896, and had practised since that time. This, the Doctor thought, was enough. The trial court thought so too. For when, in the course of the trial, the defendant offered to prove that the Doctor was not a registered or licensed physician in Kings County, the judge refused to admit the evidence, saying, "It makes no difference as to his being registered or not. The registry of physicians is only a police measure, and does not affect a physician who is really practising; an admitted physician may practise his profession; registry is only a supervision by the police." But it happens that the Public-Health Law (Laws of 1893, chapter 661, sections 140 and 149) declares that no person shall practise medicine "unless previously registered and legally authorized, or unless licensed by the law regents," that the license shall be registered in a book in the County Clerk's office, and that the violation of these provisions is a misdemeanor. Accordingly, the Brooklyn Appellate Division of the Supreme Court set aside the judgment obtained by the Doctor, on the ground that "it is a settled principle that one cannot receive compensation for doing an act which is forbidden by law and is a misdemeanor. The contrary rule would make an absurdity. It would permit one to hire another to commit a misdemeanor, and would compel the payment of the contract price for doing what the law forbids."—*Evening Post.*

PHILADELPHIA.

Protective Union of Doctors.—Physicians in Lackawanna County, Pa., following the example of their brethren in Detroit, are trying to organize a union for mutual protection. They wish to circumvent dead-beats. To compel the expert delinquents to settle up is one of the purposes of organization. Another prominent purpose will be the suppression of quackery. Lay obstetricians who do not fully comply with the requirements of the law will be an especial target for the attacks of the doctors' union. Osteopaths, who are not recognized by the law in Pennsylvania, and who, it is claimed, subject themselves to arrest if they take a fee for their service, will be closely watched. Christian Scientists, Dowieites, and all others who practise faith curing will also be objects of particular solicitude.

Dentists at the Philadelphia Hospital.—The directors of the Department of Charities and Correction of the City of Philadelphia have established at the Philadelphia Hospital a dental visiting staff consisting of four dental surgeons. The members of the staff elected are M. H. Cryer, M.D., D.D.S., University of Pennsylvania, Robert H. Nones, D.D.S., Medico-Chirurgical College, Thomas C. Stellwagon, Jr., D.D.S., Philadelphia Dental College, I. N. Bromell, D.D.S., Pennsylvania College of Dental Surgery. They become members of the Medical Board and will act in conjunction with them. This is the first general hospital to adopt the plan of having a dental staff. It is to be hoped that this example will be widely followed, for among the multitude

of patients who demand treatment from the general hospitals many are sufferers of disturbances that belong rather to the province of the dentist and oral surgeon than to that of the general surgeon.

University of Pennsylvania Medical Society.—The officers recently elected for the ensuing year are: President, Dr. John H. Musser; Vice-Presidents, Drs. W. G. Spiller and Alfred Stengel; Secretary, Dr. A. O. J. Kelly.

High-Priced Milk from Diseased Cows.—A herd of 95 cattle at the Reedhurst stock-farm near Erie has been condemned by State Inspector Irons. The animals are suffering from tuberculosis and will be killed at once. Milk from this herd has been commanding a price higher than the average because of its supposed excellence.

Bequest to Charities.—The will of Eben C. Jayne, a member of the firm of Dr. D. Jayne & Son, patent medicine manufacturers, who died a week ago, bequeaths legacies amounting to $7500 to local charitable institutions.

State Hospitals for Consumptives and Epileptics.—The State Board of Charities, at a recent meeting in Pittsburg, considered the advisability of State institutions for the care of consumptives and epileptics. All the members individually favor the project which may result in a recommendation being made to the next legislature for the establishment of such hospitals.

Typhoid Epidemic Abating.—The epidemic of typhoid fever at Cementon is abating since sanitary precautions have been instituted and all milk and drinking-water boiled before they are used. There are still 150 people ill with the disease. A press cause is said to have been a dead horse which has been discovered in the reservoir in an advanced stage of decomposition. The next move is to discover who is responsible for such an occurrence.

Skylight Falls in Hospital.—A lucky accident, in point of time, occurred at the Jefferson Hospital during the night of November 24th. A section of the sloping skylight over the operating-room fell and carried with it a large pane of a horizontal window beneath it, both falling forty feet into the amphitheater below. Some of the globes on the chandelier were broken and three tables, one, the operating-table, being badly damaged. Had the accident occurred during a clinic the persons in the arena as well as a number of students would have been seriously and probably fatally injured.

Obituary.—Dr. A. L. A. Toboldt died November 22d of uremia. Dr. Toboldt was born in Germany in 1860, coming to Philadelphia in infancy and graduating from the University of Pennsylvania in 1880. Several years later he was appointed professor of Materia Medica at the University, which position he held until four years ago, when he resigned in order to devote his entire time to private practice. He was the author of numerous journal articles.

Benefited by Christian Science.—The Coroner's inquest upon the body of Henry Mohn, who died last week of tuberculosis, revealed the fact that Mohn had had no medical treatment since June last. Since that time he had been under the care of Christian Scientists. His mother testified that their Bible readings, etc., had been of service and improved his condition because it lessened the pain and made him more comfortable. She further stated that the scientists made no charge for their treatment.

Political Pull vs. Merit.—Acting Chief Druggist England of the Almshouse has resigned his position. His letter to the Department of Charities and Correction is decidedly to the point. He says in part, "Apparently preeminent merit is 'not in it' with preeminent political 'pull' even in the selection of a man to compound drugs and medicines for the city's poor, sick and dying." England has been first assistant druggist at the Almshouse for seven years and for the past eight months acting chief druggist. He is said to have passed number one in the civil service examination against thirteen contestants for the place and to have had the recommendation of the Superintendent. It appears that another man was chosen because of political backing.

Philadelphia as a Greater Medical Center.—Superintendent Geary, at a recent meeting of a Committee of Councils at the Almshouse, suggested radical changes which would not only benefit the sick poor of this city, but would also increase its facilities as a great medical center. He advocates the removal of the pauper and chronic insane inmates to buildings which would be erected near the present House of Correction. This would make the institution what it was intended to be and should be, the Philadelphia Hospital. It could then be made the head of the Bureau of Charities where all cases could be admitted, examined, and sent to their proper places. This would make it a great medical center where many students could finish their education instead of going abroad for that purpose. To further this end the Municipal Hospital could be removed and added to the equipment, as the site of the Almshouse is an isolated one and admirably fitted for the handling of contagious diseases. This would also remove the objections of citizens to the placing of such a hospital. A hospital-boat to ply between the hospital and the Holmesburg institutions to distribute the cases needing removal would complete this arrangement.

Parasitic Hemoptysis.—Dr. Charles Wardell Stiles of the Bureau of Animal Industry, Washington, D. C., was the guest of the Pathological Society November 22d and read a very complete and instructive paper on the above subject. The exciting cause of this condition, the parasite

known as *paragonimus westermanii,* was minutely described as to its structure and development and microscopic specimens exhibited. No case of this infection has as yet been discovered in man in this country, but from 50 to 100 cases in hogs have been found and investigated by the Bureau, and it also occurs in other animals. The disease is very likely to be confounded with pulmonary tuberculosis. It is rendered of especial interest at the present time when United States troops are returning from the East. Being an Asiatic disease, occurring in man in China and Japan, the possibilities of its being brought by the soldiers are very great. The parasite passes through a certain species of snail as intermediate host in its development. While it is not certain that the species of snail which fosters the parasite in Asia is present in this country, it is known that the genus is found here. The disease is therefore not contagious, but is indirectly infectious. It is probably contracted from snails or from drinking-water. The pathology of the disease is not as yet well worked out, but it is known that both the parasite and its eggs may be carried to the brain. The diagnosis is made by examination of the sputum, which contains the characteristic eggs. Prevention consists in caring for the sputum and in destroying infected cats and dogs. The Government allows the meat from animals the lungs of which contain the parasite to go upon the market, the lungs being consigned to fertilizer plants. Treatment of the disease thus far is absolutely hopeless.

In response to a suggestion by Dr. Beates that the Society take some action regarding the placing of medical zoology in the curriculum of medical schools, Dr. Stiles outlined a course which he believes should be instituted in every medical college and taught by a medical zoologist. At present only three institutions in this country have such a course, *viz.,* Johns Hopkins, the Army and Navy School at Washington, and Georgetown University.

CHICAGO.

Cadaver Stealing at the County Hospital.—A well-developed plot for the obtaining of cadavers from the Cook County Hospital was nipped in the bud last week by the arrest of the principal.

College of Physicians and Surgeons.—Dr. William E. Quine, Dean of the College of Physicians and Surgeons of Chicago, has given $25,000 to the college to endow its library; and Dr. D. A. K. Steele, another member of the faculty, has given a like amount to endow the pathological laboratory.

Election Bet to Hospital in Danger.—George H. Laflin of Chicago, whose gift of $5000 to a hospital in New York in the event of McKinley's election was announced in a dispatch from the East, is ill at his home from the effects of a street-car accident.

To Teach Military Surgery.—Dr. Nicholas Senn has been engaged by the University of Chicago to give a series of lectures at the university upon "Military Surgery." These lectures will begin next fall, when the first-year students at Rush Medical College will study at the university instead of at the West Side College. This move has been decided upon since the Rush Medical College became affiliated with the university. A number of medical students are now taking studies at the university, and next fall there will be several hundred there.

Municipal Lodging-House.—The Commissioner of Health announces that his forthcoming estimates will contain an item of $20,000 for a municipal lodging-house, to be established in some rented building and to contain perhaps 300 beds. Such an institution might be designed, after the example of British cities, to serve the purpose of the ordinary common lodging-house which is run for profit, but evidently the proposal contemplates one which shall be of that specialized sort designed to serve as an agency in dealing with the question of vagrancy. There is to be a medical sanitary inspector included in the staff and other officers with salaries to look after the health conditions of the enterprise.

Report on Health in Chicago.—According to the statement of mortality for the week ended November 17th, the excess of deaths of males over females was 55 per cent. and of those over sixty years of age was 40 per cent. greater than during the previous week. This is attributed to the excitement in the closing days of the Presidential campaign and to exposure on election night—the principal causes of death being bronchitis and pneumonia at all ages, and Bright's disease, heart-disease, and nervous diseases among the old. Notwithstanding this excess, the November mortality-rate continues to be low.

Anti-Noise Ordinance Killed.—One of the acts of the Council last Monday was to kill the proposed ordinance for suppressing needless noises in Chicago. The measure was treated by the "gang" as a huge joke, and its discussion was carried on to an accompaniment of pounding, shouting, and general uproar. It was scarcely to be expected that the ordinance would be passed, or that it would be enforced if passed, but the spirit in which it was howled down is no credit to a deliberative body making pretensions to dignity. The facetious amendments and noisy demonstrations of the Aldermen opposed to the measure were not so funny as they seem to have imagined.

Obituary.—Dr. Romaine J. Curtiss died at his residence in Joliet, Ill., November 20th, after a short illness. He was a friend of the late Dr. Keeley and assisted him in the work of making his cure for drunkenness. Dr. Curtiss was born in Richland County, O., October 1, 1840. In 1862 he entered the Union army as hospital

steward of the One Hundred and Twenty-third Ohio Volunteers and in April, 1863, he was appointed a medical cadet in the regular army. He was appointed assistant surgeon in the navy, serving till the close of the war. He then located in Erie County, N. Y., where he practised medicine for seven years. He came to Joliet from Erie County in 1873 and resided there from that time.

Chicago a Dumping-Ground for Dependents.—The Chicago Bureau of Charities says in its last annual report that this city has become the "dumping-ground" for the chronically dependent people of surrounding counties and States, who are shipped here to relieve the persons or communities whose duty it is to take care of them of the burden of their maintenance. The board says that the city and county authorities will not undertake the duty of sending these dependents back where they belong, and that private charitable organizations have attended to the matter in many instances. The report of the bureau does not tell what excuse the local authorities make for their failure to perform their duties. Possibly they do not attempt to make an excuse. As this city has become a harbor for tramps and criminals, so has it become one for those who are obliged to live on charity or who prefer to live in that way. Dependents are sent here, or come here of their own accord, to become a burden on the public or private benevolence of this city. The down-town streets swarm with beggars whom the police allow to ply their trade. The charitable organizations, secular and religious, are deluged with applications for aid, and much money goes to the unworthy at the expense of the worthy. The practice of making Chicago a dumping-ground for outside dependents is one which imposes a heavy tax on the people of this city.

Gift to Wesley Hospital.—The building fund of Wesley Hospital is $25,000 richer on account of the subscription of Thomas Kent. The hospital is being built by Northwestern University as a cooperative institution to the medical college at Dearborn and Twenty-fifth Streets. The gift of Mr. Kent was announced last week, although it is said that he made the donation some time ago. Wesley Hospital, when completed, will cost in the neighborhood of $250,000 and will accommodate 300 patients. The main part of the building is now being erected and a small wing on the south will be built later. The cost of the main part will be $200,000 and the subscriptions which have been received so far go to make up this amount. The main building will accommodate 250 patients. Secretary Burch has collected nearly all that is needed for the completion of this part of the building. Out of the $200,000 required only $15,000 or $20,000 is lacking.

Mental Hydrophobia.—The daily press announces the death of a J. R. Beart of this city, who was bitten by a dog last August. The dog did not have hydrophobia, but last week the patient developed a marked case of hysterical hydrophobia resulting in death.

Chicago Churches Unhealthy.—The churches in Chicago, according to Chief Sanitary Inspector Young, especially the Protestant churches, with a slight exception in favor of the Episcopalian, are locked up all the time, with brief intervals for services. The result is that they are never properly ventilated, and the air becomes surcharged with germs worse than exist in any theater or worldly place. It is simply the result of the officers of the churches not properly understanding the requirements of sanitation, and how necessary it is to regard seemingly trivial things in securing a good result.

GENERAL.

Psychologists Duped.—Members of the faculties of several leading universities and colleges, eminent in psychology, philosophy and medicine, and who have attained distinction in the study of hypnotism, are indignant over the use made by the "American College of Sciences" of several articles prepared by them to be published in book form.

Oldest Physician.—According to the *Medical Press*, Dr. G. Ritter von Hochberger of Carlsbad is the oldest medical practitioner in the world. He is now ninety-seven years of age and is practising in a quiet way.

First Woman Physician in Hungary.—Charlotte Steinberger has just had conferred upon her the degree of doctor of medicine by the University of Budapest.

St. Louis Medical Society.—At the last regular meeting of this society, held November 24th, Dr. G. Wiley Broome showed two patients illustrating the transformation of senile warts into epithelioma, and Dr. H. J. Scherk read a paper on "Gonorrhea; Its Treatment from the Present Standpoint."

More Physicians for the Czar.—Three additional physicians have been summoned to Livadia from St. Petersburg to attend the Czar, the night staff there at present having proved insufficient.

Plague in Rio Janeiro.—Five hundred cases of plague have occurred in this city between April 18 and December 1, 1900.

Yellow Fever in Mississippi.—The latest reports from Brookhaven and Natchez show that no new cases have developed. The reports from Brookhaven seem to indicate that the disease has been prevalent there since September 1st.

Yellow Fever on the Texas Border.—This disease is now present 15 miles from the Texas border, in the Republic of Mexico.

Bubonic Plague in Africa.—In connection with the bubonic plague, Sir Alfred Milner, the British High Commissioner, has proclaimed that all the east coast ports of South Africa, between the tenth and fortieth parallels, are infected.

Smallpox in West Virginia.—The State health authorities have adopted more vigorous measures of quarantine at Smithfield, a small town composed principally of negroes engaged on the new Short Line Railway, 200 of whom have smallpox. Force of arms will be resorted to, if necessary.

Diphtheria and Measles in Indiana.—There are 1000 cases of diphtheria and measles in Muncie and physicians are powerless to stamp out the contagion. One-fifth of the school children are afflicted and the schools are depopulated, many having been closed.

University of Texas Medical Department.—The Medical Department of the University of Texas, Galveston, opened November 15th with an attendance almost as large as that of previous years. The date of opening was six weeks later than usual this year, therefore the session will continue until June 30, 1901. Considerable damage was done to the college building and the Sealy Hospital by the storm of September 8th, but both have been repaired. Fortunately the laboratories were not seriously damaged and the instruction will go on as usual.

Too Many Women in Medicine.—In a recent address to the students attending his courses in gynecology, Prof. Friedrich Schanta of Vienna expressed the opinion that law and other professions should be thrown open to women, because at present too many of them crowd into medicine, for which few were fitted. Of every hundred female medical students, he said, only thirty-three become physicians, the others being incapacitated by the horrors of the dissecting-room and other impediments.

Insane Man Must Pay Board.—County Judge Gower of Kankakee, Ill., decided that Luc Dandurand, insane, must pay $520 for his sustenance at the Kankakee County Poorhouse during the last five years. The decision is important, for the case is the first of its kind tried, and it will mean a saving to the counties throughout the State of many thousands of dollars. Dandurand is seventy years old, and has been insane since 1883. Seven years ago he was transferred from the eastern insane hospital to the poorhouse in accordance with the regulation that returns to the various counties all patients in excess of a certain quota. Learning recently that Dandurand had $2500 worth of property the county began suit to collect pay for his maintenance at the poor farm at the rate of $2 a week for the seven years he had been an inmate of the institution. The case was fought by Dandurand's conservator, who contended the patient was still insane, and to all practical purposes an inmate of the State hospital, and, therefore, the county could not legally charge for his sustenance.

Arsenic in Beer.—Manchester, England, is suffering from one of the most extraordinary epidemics known, which is nothing more nor less than an epidemic of arsenical poisoning and at least a hundred cases are reported. The peculiarity of the epidemic is that it has been evident only among beer-drinkers. People who have taken merely a glass at each meal have complained, though they did not connect the malady with the beverage. Since late in the summer doctors have everywhere been treating an ever-growing proportion of their patients for peripheral neuritis, which they believe due to too much alcoholic drink. In the hospital of the Chorlton Board of Guardians one ward is practically full of victims of poisoned beer. All over the Union the relieving officers have aided similar cases.

Asylum Regulations in Iowa.—Under authority conferred by the Iowa Legislature, the Board of Control in that State, which has done exceptionally good work in the management of State institutions, has promulgated rules for the government of private and county asylums for the insane. For legal reasons all these asylums had to be included in the supervision, but the abuses to be corrected are found in the county institutions. There are fifty of these latter, and they have been established as a measure of economy, the county authorities having learned that they could care for the incurable insane at a less expenditure than the amount they were required to pay to the State asylums. The economy resulted largely in stinting the number of attendants to care for the insane, in housing patients in poor quarters, and in feeding them on the products of the almshouse farm, raised by pauper labor. Hereafter there must be a proper number of attendants, not paupers, to be determined by the number to be cared for; the patients must have well-ventilated apartments, be fed three times a day, and have regular medical attendance and physical exercise, as also amusements; they must not be punished for violations of the rules; must have frequent baths and change of clothing, and the sexes must be separated.

Pan-American Medical Congress.—The triennial session of this Congress is to be held, as already announced, in Havana, Cuba, December 26, 27, 28 and 29, 1900. The secretaries of the different sections are as follows: Internal Medicine, Dr. Judson Daland, 317 S. 18th Street, Philadelphia; Surgery, Dr. W. C. Nicholson, Prudential Building, Atlanta, Ga.; Gynecology and Abdominal Surgery, Dr. H. P. Newman, 103 State Street, Chicago, Ill.; Obstetrics, Dr. E. Gustave Zinke, 13 Garfield Place, Cincinnati, O.; Therapeutics, Dr. Hobart Amory Hare, 222 S. 15th Street, Philadelphia; Anatomy, Dr. Arthur Bevan, 100 State Street, Chicago, Ill.; Orthopedic Surgery, Dr. John Ridlon, 103 State Street, Chicago, Ill.; Railway Surgery, Dr. Duncan Eve, 700 Church Street, Nashville, Tenn.; Pediatrics, Dr. I. N. Love, 40 West 44th Street, New York; Mental and Nervous Diseases, Dr. Charles H. Hughes, 3857 Olive Street, St. Louis, Mo.; Dental and Oral Surgery, Eu-

gene S. Talbot, 103 State Street, Chicago, Ill.; Ophthalmology, Dr. John E. Weeks, 40 East 57th Street, New York; Laryngology and Rhinology, Dr. G. Hudson Makuen, 1419 Walnut Street, Philadelphia; Otology, James T. McKernon, 62 West 52d Street, New York; Physiology, Dr. James P. Brubaker, 135 North 34th Street, Philadelphia; Pathology, Dr. Hunter McAlpin, 9 East 56th Street, New York; Dermatology and Syphilology, Dr. A. Ravogli, 5 Garfield Place, Cincinnati, O.; Medical Pedagogy, Dr. Otis K. Newell, 14 Central Park West, New York; Medical Jurisprudence, Dr. H. A. West, 2127 Market Street, Galveston, Texas; General Hygiene and Demography, Dr. Alvah Doty, Quarantine Station, New York; Military Medicine and Hygiene, Major Jefferson Kean, Surgeon United States Army, Quemazos, Cuba; Marine Hygiene and Quarantine, Dr. R. M. Woodward, Surgeon Marine-Hospital Service, Washington, D. C.

Information with regard to the Congress will be furnished by any of these secretaries, or by the Secretary-General of the Congress, Dr. Tomas V. Coronado, 105 Prado, Havana, Cuba, or from the American Assistant Secretary-General, Dr. Ramon Guiteras, 63 West 54th Street, New York.

Any American physician who is a member in good standing of a recognized medical society may become a delegate to the Congress by applying to the president or secretary of the society to which he belongs. Any physician in good standing in the profession may become a member by sending in his application to the secretary. Those desirous of reading papers before the Congress should send announcements to that effect to the Secretary-General in Cuba, or to his assistant in this country, or to the secretary of the section before which the paper is to be presented.

Extensive preparations have been made in Cuba for the social entertainment of the medical visitors during their stay in the Cuban capital. A number of excursions to interesting points in the neighborhood of Havana have been planned and a series of tours are to be arranged that will combine pleasure and information with regard to the possibilities of Cuba as a winter resort and will besides furnish reliable data as to the developmental resources of the country. The weather at Christmas-time in Havana is always delightful and the sea trip a source of great pleasure. The opportunity is presented for the finest excursion that medical men have been asked to take in years.

A number of the members of the medical profession from Mexico, Central America, and various South American States, especially Brazil, have already signified to the committee their intention to be present at the Congress.

The trip to Havana can be made satisfactorily in ten days, allowing time for attendance at all the sessions of the Congress. Steamers that leave New York December 22d arrive the evening of December 25th in Havana. After the Congress steamers return to New York arriving January 2, 1901.

Newark City Hospital Scandal.—There is considerable likelihood of the Grand Jury, now in session, returning either indictments or presentments against certain officials of the Newark City Hospital for alleged disregard of sanitary laws in the hospital. It was also made known that the Grand Jury a few days ago paid a visit of inspection to the hospital and gained the alleged evidence.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, November 21, 1900.

PROF. CLIFFORD ALLBUTT'S HARVEIAN ORATION—MR. FREDERICK TREVES' EXPERIENCES OF THE WAR—THE GLASGOW OUTBREAK OF PLAGUE—OPENING OF THE NEW LABORATORIES AT KING'S COLLEGE BY LORD LISTER—PAUPERISM IN ENGLAND AND WALES.

The Harveian oration at the Royal College of Physicians was delivered by Dr. Clifford Allbutt and was, as might have been expected, a brilliant production. The orator's great learning, fine diction, and above all his philosophical insight into the development of medicine from its dawn as a science under the Greeks down to the present day, were combined to produce one of the best orations that have ever been delivered on this trite subject. He began with the quotation from Baas, "Harvey stands alone in respect to the world of life; his discovery of the working of the microcosm takes a place equal to, if not higher than, those of Copernicus, Kepler, and Newton in respect of macrocosm." This judgment the lecturer said he would endeavor to show was true. He sketched the history of philosophy, science, and medicine from the time of Aristotle to that of Harvey, pointing out how greatly progress was impeded by theological dogmas and philosophical theories. Brilliant as was the promise of the Renaissance, a reaction took place in the sixteenth century not only against Luther, but against all liberal learning and science. In the Vatican, in the Sorbonne, and in the Consistory, it was proclaimed that as these studies made government more difficult it were ill to encourage them. Orthodoxy crushed free thought in Italy, and in France the ruthless religious wars had ended in the triumph of Rome. Europe was overrun by Dominicans. Almost in the year of the publication of "*De Motu Cordis*" the Parliament of Paris issued an edict that no teacher should promulgate anything contrary to the accepted doctrines of the ancients. Harvey's

discovery burst like an earthquake under Galenism and other outworn sophistries. His masterly work stood eminent not only against long-winded dialectics on *Ars Sphygmica,* critical days, and like abstractions, but also against the more lurid background of folk superstitions, magic, cabalism, astrology, etc. In physics Galileo, persecuted as he was, had some current with him and before him. Copernicus had preceded him, Kepler was beside him, but in physiology the waters had closed on the path of Galen as on the track of a great ship. The anatomists, themselves Galenists, gave Harvey little help and the share of Servetus, Columbo, and Fabricius was but small in the discovery of the central fact of the science and in the method which opened the way for Pecquet to Glisson, Steno, Wharton and Willis, to Haller and Bertrand.

In a small volume, entitled "The Tale of a Field Hospital," Mr. Frederick Treves has published his experiences at the front. With vivid pen he describes the "seamy side" of war, the horrors so well known to the army surgeon. Describing the condition at Colenso he says: "Under the shelter of the ridge, and close to the great guns, four little field hospitals were pitched." When he arrived the ambulances were coming in, "the dreary ambulances each one with a load of suffering, misery, and death. There were the very khaki-clad soldiers who had not left London so long ago spick and span amid a hurricane of cheers, and now they were coming back to the camp silent and listless and scarcely recognizable as men. They were burnt red-brown by the sun, their faces were covered with dust and sweat and in many cases blistered by the heat; their hands were begrimed; some were without tunics and their blue army shirts were stiff with blood; some had helmets, and some were bareheaded. All seemed dazed, weary, and depressed. The saddest cases were those on the stretchers on the ground everywhere. On each was a soldier who had been 'hard hit.' One man paralyzed below the waist from a shot in the spine was repeatedly raising his head in order to look with persisting wonder and curiosity at limbs which he could not move and in which he could not feel. One feature was prominent in the stricken crowd—grim pluck. There was many a groan, but never a word of complaint, never a sign of whining nor a token of fear. Some were a little disposed to curse and a few to be jocular, but they all faced what had to be like men. One man said, pointing to the overworked surgeons in the operating-tent, 'They will do what they can for the lot of us and it's good enough for me.'" Referring to the nurses he says, "These ill-housed women were hard at work all Friday, all Saturday and all Sunday night. They seemed oblivious to fatigue, to hunger, and to any need of sleep. They brought to many of the wounded and the dying that comfort which men are little able to give or are uncouth in bestowing and which belongs especially to the tender, undefined and undefinable ministrations of women."

The plague at Glasgow is dying out. Four patients have just been dismissed from hospital cured. Only 10 patients remain and these are rapidly recovering. At one time there were 25 cases of plague and 125 persons under observation. The shipping restrictions are being removed.

In the presence of a distinguished audience Lord Lister opened at King's College the new laboratories which have cost $100,000 and which place the hospital in a foremost position for pathological and physiological teaching and investigation. He said that it had been felt for many years that mere lectures were not sufficient for the student and that practical instruction was imperative. In physical science King's College had long been well equipped, but the accommodation for the teaching of practical anatomy and physiology had been for some time very inadequate. Partly by the readjustment of existing accommodation and partly by the erection of additional buildings, new laboratories had been provided. Those for the teaching of physiology were second to none in the country. The anatomical department had been extended, the dissecting-room had been almost doubled, and a fine anatomical museum had been provided in its vicinity. The bacteriological laboratory had a very important addition made to it by the opening of a new room adjoining in which research could be carried on. The means of checking the plague in Glasgow and of removing the scare of it from London was entirely due to the researches carried on in bacteriological laboratories of the world.

The annual report of the Local Government Board shows that throughout England and Wales pauperism is on the decline. But the fact remains that there is still one pauper for every 39 persons in mid-winter when pauperism is at highest level. Pauperism is here used in a very wide sense. It includes all persons relieved, of whom a considerable number were lunatics, vagrants, and children under sixteen years of age. The great problem of outdoor *versus* indoor relief is still unsolved. The persons receiving the former still largely outnumber the inmates of workhouses. Indoor relief is accompanied by great harships to the deserving poor whose lives have been honest and industrious and who at last are left without friends or relatives to assist them. They are compelled to associate with and are treated just as the lowest stratum of the population whose poverty is the result of their faults and from whom they have always kept aloof before. On the other hand, outdoor relief is attended by great abuses. In some unions, according to the inspectors, "outdoor relief" is administered in a manner which is not only extravagant and costly to the ratepayers, but which tends to pauperize the people.

DIPHTHERIA AND SCARLATINA—EARLY OPERATION IN APPENDICITIS—TREATMENT OF LOCAL INFECTIONS—WOUND CLOSURE—CHOLELITHIASIS AND GASTRIC DISEASE—OPERATIVE ASEPSIS—A NEW METHOD OF LIGATING—RENAL RUPTURE—CLUBFOOT IN THE ADULT—CAPSULE ABBREVIATION IN JOINT LESIONS—TUBERCULOUS PERITONITIS—SPINA BIFIDA—TENDON TRANSPLANTATION—INTUBATION—HEREDITARY AMAUROTIC IDIOCY—PROPHYLAXIS OF TUBERCULOSIS IN CHILDREN.

F. Wesener (Aachen) at the seventy-second convention of the Deutsche Naturforscher und Aerzte, held in Aachen, September 16-22, 1900, presented a résumé of all his observations of diphtheria and scarlatina at the Mariahilf Hospital from 1873 to 1899 both inclusive, making a total of almost 1000 diphtheria and 500 scarlet fever cases. The majority of these cases were examined bacteriologically, cover-glass preparations were made after the method of Neisser, animals were injected and cultures were grown upon glycerin-agar media and post-mortem examinations were held in all fatal cases. The culture growths were at the onset very rarely negative, and as greater skill was obtained the results were almost always positive. This was the rule especially when many plantings were made, one or more always showed the desired positive outcome. Difficulties were attendant at once upon the overgrowth of both the streptococci and staphylococci. The question of whether the pseudobacillus is a development of the true bacillus of Löffler was tested by modifying the culture media. The addition of saliva, potash and nitrites were without result, while diastase appeared to cause them to change somewhat. The experiments upon animals were successful in showing the virulence of the diphtheria; were almost always positive, a few exceptions having occurred even with cultures direct from the throats of children dead of the disease. The author contradicted the statements of Baumgarten, Gottstein and Kassowitz that the symptoms of diphtheria are not caused by the bacillus in pure infection, for in many of his patients severely sick the streptococcus was absent. In the post-mortem examinations this coccus was very frequently found. Of the 1000 cases, 206 had nephritis, which appeared in the first week in 67, second week in 128, third week in 9, and fourth week in 2 instances. Therefore he concludes that the early appearance of an albuminuria in a doubtful case tends to the diagnosis of scarlatina. Positive results were not reached in his investigations for a vegetable or animal cause of scarlatina In his view the unknown agent operates at the moment of invasion while the later factor in the clinical picture is the mixed infection with streptococci. The nephritis of this disease is regularly either catarrhal or septic or glomerulonephritis and is probably due to this coccus which was easily demonstrable in the kidneys. The hemorrhagic form secondary to a purely catarrhal is the variety most feared and is best avoided by adhering to an absolute milk diet. This is illustrated by the absence of death among all the cases of nephritis developed after admission, while it occurred eighteen times in fifty-four cases of nephritis present at admission. A forerunner of this complication was a mild angina appearing in the third week. A certain predisposition to kidney lesion exists in some families. Rheumatism and nephritis appear to be mutually exclusive.

Rosenberger (Würzburg) treats all acute cases of appendicitis with incision and drainage, ablating the organ only when it is very easily reached at the first sitting. His rules of management for the average practitioner are briefly summarized and supported thus: This operation is entirely simple and safe. If pus is present, outlet for it is thereby provided; if pus is not present, outflow for it will be at hand if the process goes on to rupture of the appendix and accumulation of exudate and secretion, which would lead up to a general peritonitis. Through this method recurrences are not absolutely provided against, because the rule is not to remove the appendix. If any fresh attacks occur it is time to do this during an interval. The operation is at that time without much danger. Large abdominal hernias are not common. His opinions were based on fifteen successful cases.

Bardenheuer (Köln) emphasized the following points in the handling of infections: The earliest possible and wide incision under general, never local, narcosis and previous tying-off of the member. Lateral incisions in inflammations of the tendons and tendon-sheaths or peritendinous regions afford better drainage and oftener spare the structures more. The sheaths must be opened only when pus is actually within them and then all care must be taken to avoid division of the ligaments of the sheaths.

Schultze (Duisburg) has been successful in closing wounds without suture and danger of infection from needle-punctures by using clamps. The wound is stretched so that its edges are in close contact. It is then clamped at intervals of about 2 cm. Gauze and iodoform collodion are next applied and when the latter is dry the clamps are removed.

Petersen (Heidelberg) reported that in 102 cases of gastric disorder cholelithiasis was the certain cause in 12 and the probable cause in 5 instances. The following anatomopathological conditions could be differentiated: (1) Pressure of the enlarged stone-loaded gall-bladder directly upon the duodenum; (2) pressure of a single large concretion from the cystic or the common duct upon the same viscus; (3) displacement of or encroachment upon the duodenum by a perforated stone; (4) pericholecystic processes,

usually hard to distinguish from perigastric processes. These operate in one or several ways combined, as follow: (1) Congestion of the duodenum by adhesion bands; (2) traction and angular deformity of this viscus or of the pylorus; (3) scar tissue contractures of the duodenum. Usually many factors are associated in each case. The most important clinical symptoms are (1) duodenal or pyloric stenosis, (2) gastralgia, (3) hematemesis due to the perforation of gall-stones or to progressing thrombosis, (4) presence of lactic acid with decrease of hydrochloric acid, which occurs oftener than with pure gastric ulcer. Pericholecystic processes and very large occluding stones may simulate carcinoma. Surgical therapeusis must fulfil the following conditions: (1) Relief of local disorders; (2) division of adhesions; (3) removal of gall-stones; (4) drainage of the gall-passages; (5) in the complicated local lesions with manifest alterations in the condition or position of the stomach must be added gastro-enterostomy; (6) duodenoplasty; (7) pyloroplasty.

Katzenstein (Berlin) reported remarkable asepsis during operations by following these few precautions. The fingers come into contact with the wound as little as possible. When they must do so unavoidably they are bandaged with sterile linen. All instruments are handled so that the part concerned in the wound is not touched. The dressings are arranged with forceps altogether and are kept in a large Schimmelbusch container, subdivided into compartments of various size which hold a given style of dressing each. His experience with the above covers two years. The same author demonstrated an apparatus for supplanting catgut ligatures with fine silver wire rings. The instrument consisted of a part for holding the rings serially and securely and another for advancing them to the clamp which fastened them upon the bleeding vessel.

Stern (Düsseldorf) reported two cases of renal rupture following compression about the lumbar region. The first was cured by free exposure and tamponade. The second was treated successfully by primary extirpation for severe hemorrhage. These cases served to exemplify the fact that every renal rupture is a law unto itself determining whether removal suture or packing will be proper.

Vulpius (Heidelberg) gave notes on 37 cases of clubfoot in patients thirteen years old or over which he had successfully treated by plastic operations in several sittings. The division of the tendo Achilles is his last step. Plaster-of-Paris fixation is continued from two to four months. Even in paralytic cases of long standing he always carries out transplantation of tendons. Among his patients 28 were treated at their fifteenth, 10 in their twentieth, and 6 in their twenty-fifth year of life. Only two cases had been lost sight of. In all the others the results were permanent.

Bardenheuer (Köln) operates for chronic luxation, weak knee, chronic traumatic hydrops of that joint, as follows. The knee-joint is widely exposed before it is opened. Through a semilunar incision the inner side of the joint is freely entered. The capsule and the ligamentum patellæ are divided outside of the synovial membrane obliquely. Then the back layer of the capsule is drawn over the front and sutured. The vastus internus is freed and stitched to the patella. The inner margin of the quadriceps tendon is lapped and sutured, thereby shortening it. The outer margin is left to itself. Thus the patella is fixed. In one case of luxation of the tibia a good result was obtained. Three other cases were still strong after six months.

Bartz (Eschweiler) reported two five-year-old cures of tuberculous peritonitis by laparotomy. The factors of any cure in his view are the hyperemic following laparotomy and a transudate rich in leucocytes. He then showed a nine-year-old boy cured of a large spina bifida by the method of Schmidt. By this procedure the large unopened sac is freed up to the hernial orifice, then punctured, inverted entirely and sutured to itself, thereby forming a tight tampon.

Frank (Köln) reported a case of rachitic clubfoot in which Bardenheuer had transplanted the tibialis posticus tendon upon the anticus and shortened the ligaments of the pronation side, namely, the deltoid ligament.

Quadflieg (Aachen) reported that in the Mariahilf Hospital of 310 sick children 43 were intubated and at the same time inoculated with antitoxin serum. Of these 24 required secondary tracheotomy, only 19 intubation alone of whom 2 died. There were 63 instances of primary and secondary tracheotomy with 16 deaths. Intubation is advised for children under one year of age because pneumonia is less likely to occur. The tube remains *in situ* two days and is then removed. More than three intubations must not be done on the same patient. The temperature regularly rises after the insertion. No intubation is done without carefully watching the patient after it, because sudden death may follow coughing the tube out. Intubation cannot supplant, but may be an adjunct of tracheotomy.

Falkenheim (Königsberg) described the lesion observed in a carefully examined and followed case of hereditary amaurotic idiocy. The parents were brother and sister in a family of decided hereditary taint that gave the direct source of the condition which in the severely affected child was the following: In the neighborhood of the macula was a gray-white blotch disappearing toward the papilla, but sharply demarked at the centrum against a dark-red spot. Another child had the same picture. In all but two of twenty-three cases were the changes about the macula primary and the optic atrophy the secondary lesion. This was a true atrophy not accompanied by any inflammation. In all the noted cases the children were at first healthy, then amaurosis began after a few months, later

paralysis, idiocy, spastic cramps and death, usually before the end of the second year. Ordinarily the disease affects several members of a family, for example, he has seen four families with four cases, five with three, one with five and four each. The course of the disease is very irregular and often interrupted. Systematic use of the ophthalmoscope will discover the disease more frequently than might be supposed, but only in the families of Jews.

Feer (Basel) stated that tuberculosis afflicts 50 per cent. of all invalids, 30 to 40 per cent. of all children in a latent form not counting frank forms, reaches its maximum death-rate among children between the first and second years, gradually recedes up to the fifth and touches its lowest level from that to the tenth year, and is very rarely congenital. Therapeutic measures are of very little value, consequently prophylaxis is all the more important, especially among children. Many obscure sources of infection can be stopped. The greatest means are food and air. Attention must be given to secure good food, pure air, hygienic surroundings, abstinence from marriage among tuberculous individuals, and breast-feeding only by sound nurses and mothers. Tuberculosis is a disease of dwellings and increases in direct ratio with the increment in the density of the population. The erection of tenement barracks and rear-houses should be legally forbidden; wide, clean streets are desirable, roomy dwelling quarters and the best room devoted to sleeping must be the rule. Volland has called tuberculosis a sickness of the filthy, hence we must care for personal cleanliness, best through the mother, who must be shielded from the struggle for food. Frequent changes of clothing must be enjoined, with baths and especially among the older children cold baths for their stimulation. The care of the mouth and teeth is most important and also avoidance of kissing which may readily infect. Adenoids, bronchitis, pertussis and rachitis all demand prompt and careful management. In bed a child is quite well protected, when it begins to creep and walk new dangers threaten, which clean carpets or better no carpets will do much to meet. No trains should be tolerated on women's skirts. Careful isolation of all tuberculous in separate hospitals and sanatoria is more and more advised. No family with children should keep diseased servants or boarders. The food of children must be carefully cooked, especially milk and meat. No alcohol must be given them. According to Cornet the bacillus soon dies in the sunshine and in the fresh air in a few days. This is exemplified by the fact that factory hands die of the disease much oftener than farm hands. Consequently cities should be supplied with many parks, playgrounds and open places. Probably wateringplaces are of advantage. All quarters of those dead of the disease must be fully disinfected and promiscuous expectoration enjoined. Systematic instruction of the populace, adult and children alike, will be of great value in showing them how to avoid the disease by proper hygiene in their community, dwellings, person, clothing, habits, preparation of food and physical exercise. Water, sunshine, fresh air and good food are the best guardians against the disease and should be watchwords.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Stated Meeting, Held October 27, 1900.

The President, John B. Walker, M.D., in the Chair.

Prostatic Enucleation.—Dr. Howard Lilienthal read a paper on this subject illustrated by his personal experience in a recent discouraging case. The patient was a man, seventy-seven years of age, who for fifteen years had passed no urine without a catheter. His catheteral life was not without incident. While he had grown accustomed to the passage of the instrument and no reaction followed its ordinary use, at times, as the result of various causes, congestive conditions in the prostate made catheterization impossible. These recurring attacks were becoming more frequent and more threatening about the time that double castration for hypertrophied prostate was advocated by Dr. White. Both testicles were removed, but the improvement was not permanent. For a time, just after the operation, some relief was afforded, but the daily use of the catheter could not be given up and after a time all urine had once more to be drawn by the catheter. After castration, however, there was a freedom from the recurrence of acute attacks with absolute retention, which showed the removal of the testicles had not been entirely without effect.

Condition Before Operation.—For the last four years the patient had been suffering from septic cystitis with offensive urine and deteriorating general health because of the constant absorption of septic matter from the bladder. Careful examination showed that his prostate was considerably enlarged, though not so much as might have been anticipated from the severity of his symptoms and the absolute necessity for catheterization. The prostate was, however, very hard and the conclusion was that the hypertrophy was fibrous in character. It was suspected that the middle lobe was especially involved in the enlargement. This would produce a valve-like effect with complete closure of the urethra except when this lobe was pushed out of the way by an instrument.

Fuller's Method.—The removal of the prostate was accomplished by Fuller's method. This was selected because it promised the best hope of permanent relief with the least danger from hemorrhage and with a free opportunity to see

the condition present in the prostate. The patient was old and weak and loss of blood was above all to be avoided if a successful result was to be obtained. When the suprapubic incision was made the condition of the prostate was found to be almost exactly that which had been suspected as the result of the examination. The ball-valve action of the middle lobe was especially noticeable. The mucous membrane over the prostate was incised and the prostate pushed well up by an assistant's finger in the rectum. The left and middle lobe of the prostate were removed together and the right lobe was taken away. At no time during the operation was there alarming hemorrhage. Whatever bleeding there was ceased spontaneously when the operation was completed. In these cases of fibrous hypertrophy of the prostate the gland shells out easily from its connective-tissue capsule and hemorrhage is usually not severe. An opening in the perineum was made in order to secure thorough drainage. For some reason this did not prove satisfactory. Drainage was then effected through the suprapubic opening by continuous syphon action. The wound in the perineum was allowed to close as soon as it was found that successful drainage could be accomplished without it. The abdominal opening was allowed to heal up gradually, and in four weeks the patient was relieved of the inconvenience of drainage by this avenue.

The Results of Operation.—The operative results have been most satisfactory. For twenty years the patient has not been able to pass urine voluntarily. He is now able to urinate freely and passes a good stream. There is slight tendency to incontinence of urine which causes some dribbling at night, but even this is growing less as time goes on. About one ounce of urine is retained in the bladder and at times no retained urine can be found at all. The patient is able to hold his urine for three to four hours and then passes it perfectly normally.

Fibrous and Soft Hypertrophy.—Cases of fibrous hypertrophy of the prostate are those that promise the best measure of success for operation. The enucleation of a fibrous prostate is accomplished rather easily and without serious danger from hemorrhage. Prostatic hypertrophy of the softer varieties are not suitable for enucleation. Complete removal of the gland is difficult, more cutting is required and there is more danger of a hemorrhage. It is probable that in these cases the burning of a groove in the prostate will prove to be the best operation. These grooves need not be burned in the dark at the depths of the urethra, but should be made under the direction of the eye after a suprapubic incision. The future of prostatic surgery does not depend on the employment of any one ideal method for the treatment of all enlargements of the prostate, but in the proper selection of that one of various methods of treatment most suitable for the special case.

Discussion of Cocainization of the Spinal Cord.

Unsatisfactory Cases.—Dr. Egbert Grandin gave the details of two cases in which he attempted to operate during anesthesia by spinal cocainization. In these cases the method had failed utterly to fulfil the promises made for it. In the first case he wished to do a curettement of the uterus and make an exploratory abdominal incision. The patient was blindfolded, her ears were stuffed with cotton, she was placed in an exaggerated bicycle position and three attempts were made by the expert in this form of anesthesia to insert the needle into the spinal canal. This was finally accomplished and after the usual wait of ten minutes the curettement of the uterus was begun. Pain was not experienced and this operation was accomplished very satisfactorily. After this the patient was placed upon her back and the abdominal incision was begun. The cutaneous and tendinous tissues were not sensitive, but the moment the peritoneum was touched there was a howl of pain. Every time that an attempt was made to incise the peritoneum this was repeated and it was found impossible to continue the operation under the cocaine anesthesia. The cocaine expert suggested a second injection into the cord, but as this would necessitate putting the woman sitting up in the bicycle position once more and as there was already an incision in her abdominal wall down to the peritoneum the suggestion was not accepted. The exploratory laparotomy was continued and completed under chloroform anesthesia. In the second case a posterior vaginal section was attempted and was accomplished without difficulty. There was some vomiting just before and after the operation was begun. An eery feeling caused by operating on a conscious individual was one of the experiences of the operator. Such feelings have been described by the older surgeons who operated before the introduction of anesthesia. It does away with a certain sense of security and freedom to continue the operation that the presence of general anesthesia gives. After neither of these cases was there any toxic reaction from the cocaine. It was not followed by rise of temperature, headache, depression nor vomiting. During the interval between the giving of the injection and the coming on of anesthesia there was in each case a tendency to vomiting. On the whole, Dr. Grandin's experience with spinal cocainization is not satisfactory and he would wish to hear further on the subject.

Favorable Cases.—Dr. Brewer said that he had had personal experience with spinal cocainization in six cases. In the first he failed to reach the cord and produce anesthesia because the needle was not long enough. In the second case he injected about a sixth of a grain of cocaine into the cord and succeeded in doing an appendicitis operation with great satisfaction to himself and the patient. In a third case he in-

jected the same amount of cocaine in order to evacuate an ischiorectal abscess. This abscess had burrowed extensively and the patient was an extremely nervous individual. When the anesthesia seemed complete the patient was put in a position for the abscess to be opened. The moment an attempt was made to cut, he cried out with pain. After a wait of a few minutes another attempt to make an incision had the same result. Dr. Brewer then said aloud to the assistant to give the man chloroform. It had been understood beforehand that chloroform should not be used, but some odoriferous substitute, such as alcohol or bay rum, put on the inhaler. The patient was assured that after a few whiffs of this he would feel no pain. The cone was placed over his head and he was directed to breathe deeply. The muscular tension at once relaxed and after a few minutes, though no general anesthetic was administered, the operation could be proceeded with without difficulty. The patient said afterward he experienced absolutely no pain. He had the sensation of contact and the dragging feeling of the cutting, but no discomfort beyond this. In order to evacuate the abscess thoroughly, a six-inch incision had to be made and to get at pockets of pus sensitively inflamed tissues were rather roughly handled. In a fourth case an excision of the knee was done under spinal cocainization. The patient talked quietly, asked questions and was perfectly unconscious of any discomfort during the operation. A number of sections of the tibia and repeated sections of the condyles of the femur were made in order to secure good bony apposition, but the patient did not wince once during the sawing and it was evident that sensation was completely obliterated, even in the deepest tissues. In the fifth and sixth cases house surgeons performed operations by this method of anesthesia, under the speaker's supervision. In one case a partial resection of the foot was very satisfactorily performed and the patient was much better satisfied than if he had been put under general anesthesia. In none of these cases were there any annoying after-effects, no nausea or vomiting, no depression or fever and no headache or general disturbance. Toxic symptoms from the cocaine, such as have been noticed by some observers, were absent. Dr. Brewer is of the opinion that a fifth of a grain of cocaine may be injected into the spinal cord with perfect safety and without the production of unpleasant symptoms. The method of anesthesia by spinal cocainization is as yet *sub judice*, but he believes that it will prove a most helpful adjunct to the surgical anesthesia of the future in certain complicated cases where general anesthesia is for some reason contraindicated.

Advantage of Spinal Cocainization.—Dr. Edward M. Foote pointed out the fact that, while the method of anesthesia by spinal cocainization has not yet reached a status where it may be used in private practice, the continuation of its investigation is eminently desirable. In military surgery, for instance, the use of this method of anesthesia would prove a great blessing. The military surgeon can carry with him in a small vial all the material necessary for hundreds of cases. This would result in a distinct simplification of military field surgery and doubtless also in a great saving of life and human suffering. This prospect alone is sufficient to justify experimental work upon the subject.

Contraindications.—It has taken many years to determine the contraindications that exist for the administration of chloroform or ether, as an anesthetic. Doubtless it will be found that cocaine also is contraindicated in certain diseased states and very probably, too, that certain individuals have an idiosyncrasy for the drug. Meantime certain accidents and annoying sequelæ will follow its use in some cases because of want of knowledge as to these details. Because healthy women react well to cocaine is no sure sign that other patients may not suffer from its use. In obstetrics spinal cocainization has proved a simple, harmless, effective procedure. In the healthy perfect anesthesia can be obtained in nearly every instance, but is not so easy of attainment in certain other cases. Dr. Foote saw an operation for hernia under this form of anesthesia on an old and feeble woman at the City Hospital. The injection was made into the cord without any difficulty, and the usual ten minutes were allowed for the development of anesthesia. A certain numbness developed in the lower limbs and the skin became insensible, but the underlying tissues retained their sensation. The operation was performed, but with a great deal of difficulty and amid many complaints. The impression on bystanders was that the anesthesia was not as good as might have been obtained by the local use of eucaine. Very little depression was noted after the operation, but three days afterward the patient sank and in spite of stimulation death took place. The fatal issue was not attributed to the cocaine but to a diseased heart which gradually gave way.

Intoxication.—In a second case an operation was performed for hemorrhoids by a house surgeon at the City Hospital. The patient was old and suffered from advanced chronic nephritis. Spinal cocainization seemed indicated and the anesthesia obtained by this method was very satisfactory. Recovery from the effects of the operation itself and from the anesthetic ensued without disturbing symptoms. Three days after the operation, however, coma supervened. This was thought to be uremic in origin and was treated as such. Notwithstanding the fact that the patient was made to sweat profusely and that an abundance of urine was passed, the symptoms constantly grew worse. The breathing took on a peculiar rhythmic character, the first phase of which consisted of superficial rapid inspiration, gradually getting deeper and louder, until a climax was reached when the succeeding phase

of lighter breathing ensued until no respiration at all could be noticed. The symptoms seemed suspicious at least of an intoxication and the thought naturally occurred that the poisonous influence of the cocaine upon the breathing centers was the reason for the peculiar symptoms. It is possible, of course, that ether would prove fatal in such cases, but it seems wiser in the present state of knowledge to risk the administration of ether rather than the unknown results of cocaine on the central nervous system.

Administration.—Dr. Royal Whitman said that he had operated on children under spinal cocainization in three cases and in two of them had secured excellent anesthesia. These two children were previously operated upon under general anesthesia and expressed themselves as much better satisfied with the new method. In children at least it is not necessary to make the patient sit up in order to make the injection into the cord; they need only be turned on their sides. Dr. Brewer also said that there was no need for patients to sit up. As a matter of fact the bending forward of the spinal cord does not increase appreciably the distance between the lumbar vertebræ. This can be demonstrated upon any skeleton. There is plenty of room for the insertion of the needle, however, and it is not a difficult matter to enter the subarachnoid space.

Dr. Lilienthal said that doubtless the new method would find a place in surgical technic. It is not, however, so entirely without danger as some heedless experimenters claimed. He himself has had a patient die on the table as the result of the withdrawal of a small syringeful of cerebrospinal fluid. The case was one of suspected tumor of the brain. An autopsy was not allowed. The use of this form of anesthesia in confinement cases certainly seems unwarranted until more is known of the after-effects of the drug upon the central nervous system.

BOOK REVIEWS.

Diseases of the Intestines. A Text-Book for Practitioners and Students of Medicine. By Max Einhorn, M.D., Professor of Medicine in the New York Post-Graduate Medical School, etc. New York: William Wood and Company, 1900.

In his preface Dr. Einhorn says that the more recent English medical literature contains no monograph on this important subject of diseases of the intestines. Recent advances in our knowledge of these affections are certainly great enough to deserve separate treatment. Those who know and appreciate Dr. Einhorn's work on diseases of the stomach will realize how well he is fitted to supply the gap in English medical literature and to write this continuance of the subject of disorders of the digestive tract. The book is written in a practical helpful style that cannot fail to make it of value, not only to the specialist in digestive diseases, but also to the general practitioner. The chapter on examination of the feces is especially satisfactory.

The subject of hemorrhoids receives the detailed treatment which the frequency of this affection requires. The chapter on appendicitis takes up one-fifteenth of the book and is a good index of present-day interest in apparently the most insignificant part of the intestines. The subjects of diarrhea and constipation are very satisfactorily treated. The discussion of nervous diarrhea is especially complete and can scarcely fail to be of practical service to the puzzled practitioner who often finds himself at a loss in handling the condition. The fact that nervous diarrhea can sometimes be controlled by suggestion, or, at least, by the patient's effort to avoid having stools at certain times is illustrated by several striking cases.

On the whole the book is well calculated to bring the practitioner's knowledge of advances in intestinal diseases up to date. It forms a worthy addition to the monographs on special subjects that have come from the hands of American medical specialists.

The International Medical Annual and Practitioner's Index. A Work of Reference for Medical Practitioners. 1900. Eighteenth Year. New York: E. B. Treat and Co. Price, $3.00.

This volume upholds the reputation of the series already well established by the preceding volumes. The first sixty pages are given up to a dictionary of new remedies and a review of therapeutic progress during the year 1899. The rest of the volume is devoted to new treatment in medicine and surgery. Many of the remedies mentioned in Part I. as new were, however, new previous to the year 1899, while some remedies which were first given to the profession in that year are not mentioned at all. The part on new treatment will prove of value to general practitioners, embracing as it does the results obtained by eminent investigators in all parts of the world. There are also a number of original articles from the pens of well-known authorities. The many references which accompany the articles and abstracts, each necessarily brief, give the volume additional value as a reference book to those who have access to a medical library. The articles cover a long list of diseases and symptoms—practically the whole field of medicine and surgery, as the volume is intended to do. They show the latest trend of medical opinion as to the best and most efficacious treatment in the various diseased conditions.

On the whole, the volume is well worth having in one's library. There are a great many illustrations from photographs and some colored lithographs in the book. Most of the illustrations are good, but some are mere blotches of ink.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, DECEMBER 8, 1900. NO. 23.

ORIGINAL ARTICLES.

AN IMPROVED TECHNIC IN AMPUTATION OF LARGE RECTAL PROLAPSE.

BY GEORGE RYERSON FOWLER, M.D

OF NEW YORK

PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC MEDICAL SCHOOL; SURGEON TO THE METHODIST EPISCOPAL HOSPITAL; SURGEON-IN-CHIEF TO THE BROOKLYN HOSPITAL; SENIOR SURGEON TO THE GERMAN HOSPITAL OF BROOKLYN.

IN a case of large rectal prolapse recently under my care at the Brooklyn Hospital the following method of carrying out the procedure of amputation of the prolapse proved to be comparatively easy of performance, and was followed by a most excellent result. The patient was a male in whom the mass protruded about five inches, and had been in existence for five years.

Analgesia was effected by means of spinal cocainization. The patient was placed in the combined lithotomy and Trendelenburg position. Being fully conscious he was able to bear down forcibly and extrude the prolapse fully, thus doing away with the necessity for traction upon the latter. A row of fenestrated or ring-headed forceps (common artery clamps will answer, but do not hold so well) was placed just in front of the junction of the mucous membrane with the skin of the anus in such a manner as to pinch up a circular fold of the mucous membrane of the outer cylinder for the entire circumference of the gut. About half an inch in front of this again an incision was made, likewise for the entire circumference of the outer cylinder of the gut, this incision extending through the mucous membrane only. Its proximal edge was dissected back for a half-inch. Two clamps were now placed, one upon either side, at the point of the prolapse, or the place where the outer cylinder of the gut returns to form the inner cylinder. With the mass thus steadied and the two cylinders identified, the index finger of the left hand was passed up the inner cylinder, and with this as a guide the circular incision already made in the circumference of the outer cylinder was deepened to the extent of a half-inch so as to include the remainder of the thickness of the latter and the inner cylinder through its entire thickness to the finger inside the latter. A suture of catgut was now placed so as to include the entire thickness of the two cylinders where the half-inch opening was made, with the exception of the turned-back mucous membrane cuff at the anal mucocutaneous margin grasped at first by the fenestrated forceps. This step of the operation was repeated until the entire circumference of the cylinders was transversed, save that each subsequent suture was first applied and the incision extended afterward. Care was taken that each extension of the incision was carried no farther than the area previously secured by the suture. Throughout this portion of the operation a stream of warm borosalicylic (Thiersch) solution was kept playing upon the parts. When the posterior portion of the circumference was reached the mesenteric attachment of the gut was encountered. This was treated precisely as the anterior portion, no difficulty being encountered in securing the vessels of the mesentery in the suture. As the last suture was applied the final cut was made in front of it, completing the amputation of the prolapse. The dissected-back mucous membrane at the mucocutaneous margin, which up to this time had been held in the grasp of the forceps first applied, was now replaced and sutured in position over the first row of sutures. Alcohol-boiled catgut was used as suture material throughout the entire operation. The patient suffered not the slightest pain during the operation, nor inconvenience either then or thereafter from the spinal cocainization, save slight nausea and mild headache. An opium suppository was placed high up in the bowel, and the parts replaced. A light tampon of zinc-oxide gauze was placed in position for forty-eight hours, after which it was removed and a castor-oil cathartic given, followed in three hours by a sweet-oil enema.

The advantages of this method consist (1) in the use of the combined lithotomy and Trendelenburg position, in order to prevent the descent of the small intestines during the operation, and thus providing against injury to these during the suturing; (2) in turning back a cuff at the mucocutaneous margin for the purpose of preserving the normal conditions at the rectal outlet, and at the same time permitting the removal of all the relaxed and overstretched mucous and submucous structures at this point. This cuff also provides a covering for the sutured edges of the stump of the prolapse and diminishes opportunities for subsequent infection; (3) in the step-by-step application of, first, a suture and then an extension of the incision through both cylinders to correspond with the sutured area, in this manner avoiding exposure of the peritoneal cavity to infection.

It is not claimed that this operation possesses all of these advantages exclusively. Several of them are features of one or another operation. I do not remember, however, to have seen them all combined in one procedure before.

A MODIFICATION OF THE MOSQUITO THEORY.[1]

By CHARLES R. GRANDY, M.D.
OF NORFOLK, VA.

I do not believe there is a single physician in this Society, who has not given some thought to the subject of the causation of malarial fever, with especial reference to the mosquito as an active agent in its dissemination. There is naturally a wide difference of opinion on this subject, and physicians have as usual divided themselves into two classes—those who do and those who do not accept the mosquito theory, but the line of division between the two factions is more sharply drawn in this discussion than is usually the case. On one side we find a number of younger men, who have used the microscope and who have had hospital and laboratory experience with the fever; while on the other side are the men who have lived their lives in places where malarial fever eternally dwells, and who have exerted their best efforts in combating it. The first class, the progressive, but at times too enthusiastic class, has adopted the mosquito theory. But the second class looks on it with doubt and distrust, and, while allowing that mosquitoes may at times cause the fever, it is not prepared to accept them as the sole method of spreading this disease, and indeed many physicians claim that the mosquito has nothing whatever to do with malaria.

In order to obtain the opinions of the men of this latter class, a circular letter was sent to many of the country physicians practising in Eastern Virginia and North Carolina—men with large experience with malarial fever in all its varieties, and the answers of some sixty of them have been tabulated and much valuable information has been acquired as the result. It is a noteworthy fact that among the sixty who answered only one person was found who believed that the mosquito theory accounted for all cases of malarial fever. Why is it, then, that these men all look with skepticism on the mosquito theory? Its warmest advocates say that they of the other side do not understand it, or that they are prejudiced. But, while this is certainly true in many instances, there are still a large number of men with wide experience and good judgment who claim that this theory does not explain all the existing conditions, and who, although they acknowledge that mosquitoes can directly transfer malaria from one person to another, believe that this theory cannot possibly account for all of the cases of malarial fever. We must not forget, however, when criticising the mosquito theory, that its originators do not claim it to be proven that malaria can only be transferred directly by the mosquito, although they evidently believe that this is the case.

[1] Read at the meeting of the Medical Society of Virginia, held at Charlottesville, October 23, 1900.

It will be well, in discussing the mosquito theory, first to state what it is in a few words, and then to criticise it in the light of existing conditions, and see where it applies and where it does not apply. Briefly it is this and it has been demonstrated to be possible by actual experiment. If a mosquito of the genus *Anopheles* takes malarial blood into its stomach, the malarial organisms, having freed themselves from the corpuscles, invade the stomach-walls, develop there, and in about ten days' time produce a number of young organisms, which pass through the blood-vessels into the parotid glands of the mosquito. They can then be injected into the blood of another person, who after some little time develops the same variety of malarial fever as the man from whom the original parasites were taken. It is only in mosquitoes of the genus *Anopheles* that the plasmodium can develop, the *Culex* being entirely incapable of transferring the disease.

In considering malarial fever, or any other disease for that matter, we must not forget the personal equation, although it often seems to be entirely lost sight of in a discussion of this sort, for Nature has always provided means by which the body can combat disease, even though it be often unsuccessful in its attempts. Thus in a healthy, vigorous man, who has not had a very large injection of malarial organisms, the leucocytes can often destroy all or most of the plasmodia, or can keep them down so as to prevent them from producing symptoms. Then it is necessary for some external cause to lower the bodily vigor, before the organisms can attain sufficient numbers to produce appreciable symptoms. It is also probable that a person can become partially immune to the poison through frequent attacks or through heredity. The organisms may thus often remain a long time dormant in the blood without causing any trouble. Every one who has examined blood recognizes this as a fact; and it is likewise proven by clinical experience, when the fever returns in a week or three weeks, or when it first appears after the person has removed from a malarious district.

The mosquito theory explains satisfactorily many of the well-known conditions which have long been recognized as aiding in the production of the fever. To begin with, malaria in these regions is prevalent when mosquitoes abound, *i. e.*, in August and September. It disappears for the most part when mosquitoes disappear—that is, at frost. Cases which remain or appear in winter or early spring are attributed to latent disease, which is made active by some external cause lessening the resisting power of the body. In eastern North Carolina cases of malarial fever are found in every month of the year, but they are much more common and much more severe in late summer and early autumn. Marked changes in temperature seem to have a striking influence in bringing out this latent

malaria, which is especially liable to occur in early spring. These cases, however, are almost always mild and are easily controlled by the use of quinine. Then *Anopheles* mosquitoes have been found in every markedly malarious district. There are places where there are many mosquitoes and no malaria, but these mosquitoes, when investigated, have almost without exception been found to be of the genus *Culex*, as, for instance, I found myself to be the case in northern Michigan. Finally, there has recently come the report from Italy, that five men have lived a month in a very malarious district, working hard by day, but being protected from the mosquitoes by night; and that these five men did not contract the disease, although they took no quinine, while others, doing the same work, but unprotected from the *Anopheles*, suffered from grave forms of malarial fever.

There are, however, objections to the mosquito theory as it now stands, and the great objection to my mind is that it claims that malaria can only be propagated by the direct transportation of the organisms from one man to another. I do not for an instant contend that this does not often occur, for I consider this much a proven fact, but I cannot bring myself to believe that the mosquito alone obtains and disseminates the plasmodia in this way. This, too, seems to be the point to which the men with the largest practical experience cannot subscribe, for they do not consider it possible for all the cases of malarial fever to be produced by this direct inoculation.

There is another objection to the mosquito theory to which I have not as yet heard a satisfactory answer. It is this: If the life cycle of the plasmodium is only to be found in man and the mosquito—that is, that the mosquito takes them from one person and directly inoculates another—and if there is no other host or medium which may at times shelter these organisms, the most malarious districts could be freed from this disease by being depopulated for a year, or at most two years. My reasoning in this matter is very simple. The mosquito only lives a short time, a month at longest, except when it hiberrates. If all the infected mosquitoes died, without inoculating more people, as they certainly would do in two years' time, the most malarious district would become healthy. This, however, as far as I have been able to learn, is not in accordance with fact; there being some districts so malarious as to have made depopulation necessary, and yet it appears that if a man goes into such a region, he will contract the fever. Then, too, if an army camps in a swampy, sparsely-populated country, the soldiers contract the fever, and contract it in places where men rarely if ever come. The *Anopheles* do not seem to fly far from their breeding-places. Is it therefore likely, if malaria is only contracted through the mosquitoes, that they have all had the opportunity to digest malarious blood?

Manson believes (or believed) that the mosquitoes give up the parasites when they lay their eggs and die in the water, and that the parasites are then taken into the system by men who drink the water. This is in accordance with what he found to be true in the case of the *filaria sanguinis hominis*. The objection to this is that all the recent investigations have gone to show that malarial fever is *not* contracted from drinking water, either because the malarial organisms cannot live in it, or because they are destroyed by the human stomach secretion, just as they are destroyed in the stomach of the *Culex*. I have a very good example to the point, which I would like to add to those already published. The city of Norfolk obtains its water from ponds lying in a notoriously malarious district, yet the paved and sewered part of the city has long been almost free from malarial fever, although the unpaved and badly drained suburbs, some of which use the same water, have many cases of the fever. Then the City Almshouse, which lies near the water-works and gets its water from it, has regular yearly outbreaks of malarial fever. Last winter a very complete sand-filter plant was instituted, yet there has been no appreciable change in the malaria in any one of these places, perhaps there have been a few more cases this summer than is usual in the city. How, then, can we account for the fever? Around the ponds are found large numbers of *Anopheles* which breed in the drinking water (which, by the way, contains many algæ), and in the suburbs *Anopheles* have also been found. Where this mosquito is found, there we find the malaria; but the drinking water, filtered or unfiltered, has no appreciable effect, as the people in all these localities use the same, yet one place is almost free from malaria, while another has regular outbreaks in the autumn.

Then it has been thought that the plasmodia might pass through the eggs into the larvæ and remain till the mosquito was grown, and that they then could be inoculated by it. This seems to be true in the case of the organism that produces Texas fever and which is inoculated by a tick, but actual experiment has disproven it in the case of the human malarial organism.

There is another modification of the mosquito theory which overcomes these objections, and, although it is still mere hypothesis, it appeals to me strongly. To begin with, we will acknowledge that in a certain number of cases malarial fever is directly transferred from man to man by the *Anopheles;* so much is proven beyond question. But I believe this to be the fact in only a very limited number of cases. How then can we account for the great majority of cases of fever? I still believe in the potency of the *Anopheles,* but believe that they can, and do, obtain the organisms from other sources than direct from the human blood. We know that this genus injects the young malarial organisms from its parotid gland into the blood of the man

upon whom it is feeding. Is it not likely that it, when feeding on other things than human blood, which seems to be more of a delicacy than a staple article of diet with the mosquito tribe, should also inject the parasites into whatever it is eating? Other uninfected *Anopheles* may take in the parasites directly from this food or water; or the plasmodia, in the form in which we find them in the parotid glands, may be able to live in water or damp soil as other sporazoa do, and later on they may be taken up by other *Anopheles* and be inoculated by them into man. It is also possible that the plasmodia may pass into the water from the bodies of the *Anopheles*, which have died in the water after depositing their eggs, and may be taken up in feeding by other mosquitoes.

All the arguments in favor of the mosquito theory apply equally well to this modification, but the modification explains some points to which the original does not thoroughly apply. Let us, then, briefly criticise this modification of the theory and see if it will hold good under all conditions. Naturally many of these will apply to the theory as it now stands, as well as to its modification. In the first place wherever malarial fever regularly appears, there we find the *Anopheles*. There may be places with this mosquito and without malaria, but if the disease is brought there by man, the insect can spread it.

This has been observed in the case of an East Indian island, whither the fever was brought from India, and where let us remark it still remains. The *Anopheles* breed only in pools and not in tubs; they are the country mosquito in contradistinction to the *Culex*, which is found in both towns and country. This explains why there is so much more malaria in the country districts. They feed at night, which fact explains the influence of night air in producing malarial fever. They are most numerous at the time of the heavy dews (in August and September), the effect of which is thus accounted for. Their larvæ feed on algæ, hence the theory that stagnant water causes malaria. It has long been noted that the digging up of old swampy soil causes an increase in the number of cases of malarial fever. This can be accounted for either by furnishing fresh breeding-places for the mosquito, or possibly by the exposure of dormant parasites, which are then taken up by the *Anopheles*. Malaria is severer in warm, rainy seasons, because this both furnishes the insect with more and better breeding-places, and likewise allows it to obtain more of the extracorporeal organisms. On the other hand, the drainage of the soil deprives the *Anopheles* of breeding-places and kills the extracorporeal organisms by depriving them of moisture. The eucalyptus tree stops the malaria by driving off the *Anopheles*. It would be interesting to know if the fever would return as soon as the trees were cut down, and more especially if young *Anopheles*, raised in the laboratory and free from infection, were turned loose there. As I remarked before this modification explains how uninhabited districts still may remain malarious, and this the unmodified theory does not do. It explains how the fever is disseminated without direct reinoculation; for this would imply either very active work on the part of the infected mosquitoes which have lived through the winter, and which must be comparatively few in number, or a very large number of cases of dormant malaria, from which the young mosquitoes could obtain the parasites. Whereas the writer realizes the large number of these cases, he does not believe them sufficient to alone restock the *Anopheles* with plasmodia. It likewise must not be forgotten that most of these dormant cases seem to develop in early spring, when there are no *Anopheles* to be infected, and that they readily respond to treatment, which would destroy the parasites before the *Anopheles* would have a chance to obtain them.

The original experiments by Bignami simply showed that *Anopheles* taken from a malarious district could produce the fever in a healthy man by biting him, although his later experiments showed that they could directly transfer the parasites from one person to another. Consequently many of his experiments speak as strongly for the modification as they do for the theory, for the mosquitoes might have obtained their organisms from sources other than human blood.

There are two objections to this modification of the mosquito theory. The first is that the malarial organisms have never been cultured artificially. To this we can reply that no other parasitic protozoon has been thus cultured, and that we must not demand more in one case than in the others. The second is that they have never been found free in nature. We must consider in regard to this point how very minute are the tiny thread-like organisms found in the mosquitoes' parotid glands and how easily they could escape observation when looked for in water, let us say, and that up to the present year they would not have been considered in connection with the *plasmodium malariae*, even if found, and might readily have passed for bacteria. Experiments made with the organism as found in the human blood will have to be cast aside as proving nothing, and every experiment in regard to the extracorporeal life of the plasmodium will have to be tried with it in this thread-like stage, for it is from this stage that it passes into the external world, if it does so at all.

A positive proof of what I have just read cannot as yet be shown, and further investigation may overthrow it. Nevertheless I claim that this modification of the mosquito theory comes nearer fulfilling all conditions and answering all objections than any theory that has come under my notice. Like all hypotheses, for it is nothing else, it needs further investigation, which will either strengthen or overthrow it. Still it is at least worthy of consideration, and as such I pre-

sent it to you, hoping that it will be criticised fully and severely, for if it will not stand criticism, it had much better never go beyond the doors of this hall.

HEAT-STROKE AS A POST-OPERATIVE COMPLICATION.[1]

By C. L. GIBSON, M.D.,
OF NEW YORK;
ATTENDING SURGEON TO ST. LUKE'S AND CITY HOSPITALS.

The atmospheric conditions that occasionally prevail during the summer season in New York determine not infrequently conditions known as sunstroke and heat-stroke. The occurrence of these phenomena seems to be the result of a combination of high temperature, a high percentage of humidity and absence of breeze. The humidity is perhaps the most essential feature and certainly determines the greatest amount of depression and suffering even when the thermometer fails to register extreme degrees of heat. When the combined elements are most marked, we have in this city a climate which is badly borne even by those accustomed to live in countries where the range of the thermometer during the heated term is considerably higher than here.

All accustomed to treat the very sick realize perfectly the severe depression produced in patients by hot weather. For the past seven summers the writer has had abundant opportunities to observe these effects of heat in an active hospital practice. He believes that one ought to realize that this depressing humid weather furnishes a real complication in many cases and in some constitutes a condition of major importance directly dangerous to life.

In ascribing to the effects of heat a decided rise of temperature and definite constitutional symptoms, we must, particularly when dealing with post-operative conditions, be able to eliminate entirely the many causes that may determine a post-operative fever. Such a standard makes it very hard to reduce a description of a given case to exact language, and get to prove one's views to others, no matter how sincere one's personal impression may be. Shock, sepsis, suppuration, hemorrhage, neurotic conditions, constipation, malaria, constitutional dyscrasiæ, evident or latent, iodoform-poisoning, genito-urinary infections and reflexes, renal and many other conditions must be eliminated before one can fall back upon heat as the sole determining cause of this condition of fever and constitutional manifestations which, if sufficiently marked, the writer would describe as post-operative heat-stroke.

The writer has in mind a number of cases which he believes might come under the head of heat-stroke, but, mindful of the desirability of restricting the term to sharply-defined cases, he will confine himself to the report of two in which conflicting evidence seems to be absent.

[1] Read before the Surgical Section of the New York Academy of Medicine, November 12, 1900.

Case I.—Walter O. C., aged eight years, admitted to St. Luke's Hospital June 1, 1900, with a history of appendicular trouble of short duration. The previous history excellent. Physical examination negative except for local condition. There is a moderate general abdominal rigidity, most marked on the right side. There is a point of extreme tenderness just above and internal to McBurney's point. No mass can be felt. Temperature 102° F. Pulse 120. Immediate operation under gas and ether anesthesia. An incision along the border of the right rectus revealed a long and in part gangrenous appendix; no abscess. Removal of appendix; gauze packing; closure of the greater part of wound. The immediate recovery was good, but by the afternoon of the next day the boy presented a chain of symptoms which gave the impression that he would die in a few hours. The temperature was 104° F., pulse 148 and of wretched quality. The countenance was pinched and of an appalling ashy, gray-blue color, the skin was hot and dry. He was irrational and could not be kept still in bed. Changing of the dressings showed a perfect condition of the wound. During the course of the afternoon the condition was intensified, and the patient became wildly delirious. The house surgeon, Dr. W. P. Herrick, was fortunately inspired with an effort at a reduction of temperature by an alcohol sponge-bath and the application of ice bags to various parts of the body. The working of these measures was almost miraculous. The delirium ceased instantly, the child passing into a natural refreshing sleep of some hours, awaking in a perfectly normal condition, and the temperature dropped from 104° to 100.6° F.; the pulse fell to 98 and was of excellent quality. June 2, 1900, was an especially depressing day, although the heat did not reach some of the extremes attained later during this very hot summer, and the close and distressing quality of the air had been specially noted in the particular ward in which the patient lay. The child's further convalescence was perfectly normal.

In the case just described there was absolutely nothing but the heat to account for the symptoms; the result of treatment was promptly manifested, and the uneventful after-history showed that it was the only complication present.

The next case presents quite different elements, as there was a very grave condition giving rise *per se* to a high temperature, but its extreme degree leads the writer to believe that the heat element was an additional and definite factor.

Case II.—Mr. Charles Van E., admitted to St. Luke's Hospital August 10, 1900, with a history of appendicular trouble of a week's duration. In his previous history it is noted that he never had had malaria. Examination showed an enormously obese man, weighing over 300 pounds, somewhat cyanotic. Heart-action feeble and intermittent. Abdominal palpation negative. Temperature, 104.4° F., pulse 108. Immediate

operation. A seven-inch incision was necessary to reach the peritoneum. A huge abscess cavity was opened and the gangrenous appendix was removed; through its lumen magnesium sulphate ℥ ij, in concentrated solution, was introduced into the bowel and the stump inverted into the cecum. Liberal packing of cavity. Partial suture of wound.

An hour and a half after his return to the ward the temperature (verified by several thermometers) was 108.2° F. When this temperature was reported the writer assumed that this excessive temperature must be due to heat-prostration and instituted treatment on this line, *viz.*, rubbing with ice, ice-coil to the abdomen and head, etc., with the result that the temperature was brought down in three hours to 102.8° F., a drop of five and four-tenths degrees. For the next twenty-four hours it ranged from 102.4° to 104° F., dropping below 101° F. the second day after operation. Meanwhile the antithermal treatment had been vigorously continued. He made a poor convalescence, as his heart constantly flagged. He died rather suddenly two weeks after operation. Autopsy showed the cardiac condition alone to be responsible for the fatal result.

The writer believes that the immediate hyperpyrexia in this case may be attributed to the following facts: The patient traveled by railroad in the greatest heat of the day to reach the hospital. He was etherized in a small, close room without any window opening externally. The main operating-room being in use, the operation was performed in an auxiliary room with only one ordinary window in it, and that facing north while the prevailing breeze that day was from the south. At the time of the operation the Weather Bureau thermometer, high above the street level, registered 94° F. and the humidity was so distressing that all participants in the operation were dripping with perspiration. The day is remembered in the hospital as probably the most trying of the whole summer.

After opening this huge abscess (about two quarts of pus were evacuated) the patient should have had a drop in temperature rather than a rise. That we were able purely by the application of cold to effect a drop of five and four-tenths degrees in a short time seems to the writer, taking in consideration the etiological factors just stated, fairly good evidence of the correctness of the views here maintained.

On the Fourth of July, 1899, the writer operated on a young man with a small, well-localized appendicular abscess; the appendix was easily removed, and the cavity well drained with gauze. Three days later, after having done quite well, the patient became delirious and finally maniacal. The skin was hot and dry, the pulse-rate reached 176 and the temperature 105° F. Application of cold quickly brought down the temperature over four degrees, and the pulse to 122. The patient died, however, the next day apparently of exhaustion. There was no post-mortem, but the condition found at operation and the abdominal symptoms, or rather lack of them, did not give a sufficient explanation of the cause of death. As the weather was particularly sultry, this may have been a case of heat-prostration, but it is not offered on the same footing as the cases just related.

If the writer is correct in his belief that there is an occasional reaction to the atmospheric conditions in operative cases, it is certainly important to recognize it in order that it may be properly and promptly treated (there is no question in my mind that in the cases cited the treatment saved the lives of the patients, as they were both rapidly sinking); (2) for the surgeon's peace of mind, and (3) to avoid misdirected efforts at the relief of conditions which may be mistaken for these effects of heat.

With regard to the treatment, little need to be said except to recommend free circulation of air (electric fan), free diuresis, and the application of cold in various forms, the extent to which it is resorted varying with the urgency of the symptoms and the exigencies of the surgical condition. Probably none of these heat manifestations will ever be of a very severe type, and comparatively mild measures should succeed. The prognosis should be good, provided treatment is promptly instituted.

It is not the writer's desire to convey the impression that because of occasional manifestations, as just described, the summer season is relatively less favorable for operative work. On the whole, patients perhaps do better, as they are more free from pneumonic disturbances, the increased action of the skin supplements the efforts of damaged kidneys, and the prevailing temperature assists in maintaining a good circulation. It is only necessary to bear in mind that occasionally the beneficial effects of heat may become misdirected, if complicated with unfavorable accompanying atmospheric conditions.

CHLORALAMID.

By S. V. CLEVENGER, M.D.,
OF CHICAGO;
AUTHOR OF MEDICAL JURISPRUDENCE OF INSANITY, ETC.

NORMAL sleep occurs during the harmonious working of bodily organs. Sleeping and waking states are rhythmic life phenomena and part of the evidence that action and reaction are always equal and opposite. Further, sleep is an assimilatory process by which energy is stored for expenditure during waking hours. Therefore anything that disturbs the harmonious working of bodily organs interferes with sleep. The foregoing may sound trite or like a mere statement of fact, but when we attempt comprehensive definitions and secure axioms we too often neglect them in considering related matters.

Treatment of sleeplessness must vary therefore as widely as the nature of the disturbance of

whatever particular bodily organ is involved. If the head is too full of blood to permit sleep, resort may be had to a hot foot-bath, a laxative or other derivative means; if sleep is absent because the heart is weak, its stimulation is indicated; if sleeplessness ensues through poisonous materials retained in the circulation, proper elimination is imperative. To any one with a rudimentary knowledge of physiology such things should be apparent enough, but in spite of the dissemination of that amount of information single remedies are still expected for complex ailments such as insomnia.

Germain See's division of causes of sleeplessness are into dolorous, digestive, cardiac, respiratory, cerebrospinal, neurotic, psychic, insomnia of fatigue, genito-urinary and toxic. Reflection exposes the unsatisfactory nature of such a division, for conditions are named that could be included one in the other, and the organs mentioned are too few, while in such names as neurotic, psychic and cerebrospinal we may have identical states. Bradbury[1] classifies the causes of insomnia into irritative, toxic, psychical, change of mode of life. The first division may be made to include all the other divisions, the second may cause the third and the fourth suffice to set up any of the others.

Irritation might be assigned as nearer the root of insomnia than probably could be summed up in any other word, but what causes the irritation should be sought for and removed if possible. As it is not always practicable to find the source of this irritation we are forced to regard, in many cases, the fact that the nervous system is the avenue of irritability and attempt relief through neurotic medicines.

The claim that sleep depends upon a retraction of neurons, a drawing away of nerve-processes from one another, is not only incapable of proof but as fantastic as that skeletons may walk. In 1882[2] I anticipated the neuron theory to the extent of assigning axis cylinder producing functions to the nerve-cells, but expressly derided autonomy of nerve-tissue. The narrow specialist in neurology seems to regard the nervous system as capable of existence apart from the body.

Something nearer ultimate causes of sleep and its disturbances can be secured by considering the blood-supply states upon which they depend. I advanced a theory of sleep[3] based upon vascular changes, claiming that the whole range of sleep phenomena is accounted for in states of the blood-vessels and their contents, quantity and quality of blood and caliber differences of arterioles. What would suffice to cause sleeplessness in one person would not do so in another, and the same individual will be affected differently at times by similar causes. Mental suggestion may suffice to produce sleep in a few instances, but fails in serious cases. Humboldt is said to have required but two hours' sleep, Pitt three, Hunter five in the twenty-four. But other noted persons were not thus abnormal.

Among promotors of normal sleep may be enumerated fatigue, repletion, removal of irritation, such as disturbing temperature (remembering also that toleration of what previously irritated may be acquired, such as adjustment to noises), silence, darkness, fresh air during the previous waking hours, massage, restoration of proper circulation as by a hot bath or warmth to feet, a narrow strip of mustard plaster to the spine, a cup of hot beef-tea or of hot water, local friction between the shoulders or over the abdomen, an enema of hot water, not for its cleansing action but to impart interior heat, although in states of faulty elimination catharsis, laxatives, diuretics or diaphoretics may cause sleep. Tonics are needed or perhaps a heart stimulant in states of low arterial tension. Such are indicated by wakefulness in recumbent positions and drowsiness while erect or sitting.

While fatigue may cause sleep, excessive fatigue may destroy it and become an irritative cause of wakefulness. Irritative insomnia may be due to excessive fatigue, abnormal temperature, respiratory difficulty from organic or chemical causes, such as insufficiency of oxygen, excess of carbonic acid or other toxic material, other organs such as stomach, liver, intestines, ovaries, etc., may be deranged, as when hunger or pain is felt, or there may be sensory irritation as by noises, light, etc., cerebral congestion, circulatory derangement, as in inflammation, tumors, and in the delirium of fever or apprehension of heart-disease. Sleep may be banished by improper use of coffee or tea. Excitement such as joy or grief may destroy sleep. Pain anywhere is a frequent and potent cause of sleeplessness.

Abuse of hypnotics is frequent, as in the case of an old gentleman whose customary whisky was cut off by his physician and who lost the use of his legs and "had not slept for a week," although large doses of chloral and bromides had been given. The overdosing had caused both the "paralysis" and the sleeplessness and irritated the stomach so that food could not be taken. My advice was to stop the depressing drugs and take an egg-nog, which caused refreshing sleep in a few minutes and cured the "paralysis."

In many cases time is required to remove a discovered cause of sleeplessness and meanwhile sleep is imperative for the sufferer. In the greatest number of such and other instances there is no medicine that can equal chloralamid in efficacy. In nocturnal epilepsy and particularly where there is apprehension of somnambulism I found that chloralamid suppressed attacks. Dana[5] found it to be a useful adjuvant in epilepsy.

Where repeated doses of a sleeping-potion are to be administered I have found during the past ten years that chloralamid is without a rival, as it does not depress the heart or irritate the stomach as do bromides and chloral hydrate, nor paralyze the intestines and stupefy the next day as do sulfonal and trional. In ordinary melan-

cholia it acts as a food and I therefore classed it among "nutrient hypnotics" or those that supply some material to the system that sustains instead of depresses. In this sense milk, beef-tea or a stimulant, is a nutrient which may upon suitable occasions produce sleep. In agitated melancholia with refusal of food I gave the solution mixed with the liquids for enforced feeding and have noted in most cases a disposition to take food thereafter. In toxemic neuroses and psychoses, in which other hypnotics or analgesics added to the trouble by giving more poison to the system and interfering with elimination, chloralamid has appeared to antagonize the polluted blood-stream, strengthen the heart and bowels, and clear up the intelligence. During the formation of alveolar abscesses both the pain and sleeplessness have been greatly abated by chloralamid, and inveterate neuralgias have been made far more tolerable by occasional doses when sleep was disturbed. The distressing wakefulness of traumatic neurasthenias, especially when the spinal column had been injured or was involved in inflammatory states, has been relieved, and in locomotor ataxia I prefer chloralamid, in conjunction with derivative means, to any other medicament when there is nocturnal pain. In this disorder opium should never be given and many of the other usually suggested hypnotics will be found to be worse than inoperative. In the occasional restlessness of chronic insanities, in the sufferings of meningitis, and when senile heart conditions or, in fact, cardiac troubles in general suggest extreme care in the selection of a hypnotic, chloralamid has no rival. It acted rapidly and satisfactorily in breaking up the cocaine habit, and a drunkard who used it stated that a few doses deprived him of his appetite for liquor (how long I did not learn), nor was there any disposition to take further doses afterward. Too many alleged "cures" of addictions merely substitute one pernicious habit for another. Charteris[6] and Ledingham[7] favor its use with bromides to prevent seasickness. Keay,[8] Strahan[9] and Umfenbach[10] advise its use in mental diseases. Manchot[11] suggests it in diabetes. A large number of competent clinicians have endorsed chloralamid favorably.[12] Hagan and Hüfler observed good effects upon sleep even when sleeplessness was due to severe pains, being in some cases even superior to morphine, and Collins mentions its usefulness where any pain prevents sleep. Where there is excessive irritable activity of the brain it has given relief. In a case of sleeplessness from arterial sclerosis chloralamid relieved when morphine failed to do so. E. Friend found it better than morphine in the distress of gonorrheal rheumatism. Pain and consequent sleeplessness in thoracic aneurism were relieved when morphine failed, and Reichmann used chloralamid in gall-stone pain in preference to morphine. In various neuralgias and carcinomatous suffering, in the pain of floating kidney, herpes zoster, alcoholic neuritis, dysmenorrhea, etc., chloralamid was proven to be superior to morphine. In Bright's disease, where sleep had been seriously disturbed by almost constant headache which various remedies failed to remove, chloralamid was beneficially used and in the sleeplessness of phthisis it was noticed that the exhausting night-sweats were lessened. It relieved the severe headache of contracted kidney. Some writers mention its soothing influence upon mental disorders.

Manchot in the Hamburg Lunatic Asylum used more than a pound of chloralamid monthly for forty months in doses of 112 to 180 grains daily, mainly in delirium tremens and chronic alcoholic cases. His mortality during this time fell from 6 in 160 to 5 in 519 uncomplicated delirium tremens cases.

A few instances of undesirable after-effects have been stated as occurring after using chloralamid, *viz.*, headache, stupor, giddiness, exhilaration, intoxication, nausea, incoordination, slight pain, dryness of throat, stomachache, epistaxis, measles like exanthem, and sugar in the urine as an idiosyncrasy, but not constant in all cases, and in only one-third of the cases where large doses were used. These accompaniments are in so few instances as to suggest coincidence rather than cause. I observed exhilaration and slight incoordination, however, in a cocaine case, and to a less extent in alcoholism the day after chloralamid had been used, but these were of no consequence compared with the benefits secured.

Alt found it of little use in the excitement of mania or paretic dementia; I recorded, in the 1894 article referred to above, that the drug appeared to answer best in the depressed psychoses and did not seem to be strong enough for mania. This I attributed to its stimulant influence, needed in melancholia to induce sleep, but superfluous in mania, although sustentation is imperative in both conditions.

It is to be noted that inferior whisky is not a rapid solvent and it is recommended to dissolve the crystals in a little pure alcohol and then add water or whatever is preferred. The elixir is therefore a prompt means of exhibition where time is a consideration.

Pharmacists keep a ready made elixir in stock with the following composition containing 30 grains to the fluid-ounce: Chloralamid, 2 grams; alcohol, 5.0 c.c.; tincture arom., 5.4 c.c.; glycerin, 15.0 c.c.; water q. s. ad. 30.0 c.c.

Chloralum-formamidatum, the chemical name, which pharmacy requirements shorten into chloralamid, is constructed by the interaction of chloral (not chloral hydrate) and formamide. It dates from the experiments of Von Mering, the Strasburg clinician in 1889, and has grown into universal esteem. The Pharmacopœias of all other nations will assuredly follow the German in recognizing its value. The formamide is a stimulant which counteracts the blood-pressure fall of chloral and, according to Reichmann's sphygmographic tests, chloralamid influences

blood-pressure but little. Nor is there unfavorable action upon the temperature, respiration, circulation or digestion.

It is decomposed by alkalies and heat and in water at 140° F. (60° C.), hence it should never be given in hot water as has been improperly done at times. Twenty parts of water at ordinary temperature are said to dissolve the crystals, but I have found that 30 to 40 parts of water save much time in making the solution; weak acids facilitate its dissolving and one and a half parts of alcohol rapidly unite with it; therefore, about three parts of brandy or whisky, if standard, will also do so. Taken in powder the effect is delayed, though some practitioners persist in this form of dosing. With stomach acidity there would be more rapid assimilation. Claret is used occasionally, but in all instances where vinous or watery vehicles are solvents and time is to be saved a concentrated alcoholic or elixir dose should be poured into the vehicle.

Its slightly bitter taste is scarcely worth consideration, but to disguise it an approved formula is:

℞ Chloralamid ..... ʒ ij
Whisky ..... ʒ j
Syrup raspberry ..... ʒ j
M. Sig. Half-teaspoonful dose.

Lettow's prescription for an enema is:

℞ Chloralamid ..... gr. 45
Muriatic acid ..... gtt. 2
Alcohol ..... ♏ 15
Water ..... ʒ iij

A solution made with 12 grains in two and a half drams of water may be used hypodermatically when such disorders as rectal carcinoma deprive a patient of sleep.

The usual dose of chloralamid is 15 to 60 grains one half-hour before bedtime. It takes effect usually in one hour. One dose has sufficed to secure sleep on a subsequent night as well as upon the night when used. The German Pharmacopœia mentions 60 grains as the largest single dose and 120 grains as the largest daily dose.

There is no liability to addiction, no ill consequences, no cumulative effect, and as it does not influence the viscera and is not an irritant to any mucous membrane it should more rapidly supersede chloral hydrate, as it is gradually and surely doing.

The relative strength is assumed to be 45 grains of chloralamid equaling 30 grains of chloral hydrate, but in practice the doses are about the same with the advantage that while a minimum dose of chloral hydrate has killed, no amount of chloralamid has been attended with fatal result so far as reported. The blandness and safety of chloralamid without after-effects should certainly recommend it against the danger and harshness of chloral hydrate which destroys digestion by setting up gastritis, and its constant administration has cut off chances of recovery from insanity. I believe that insane asylums should in the name of humanity use chloralamid in preference to chloral hydrate. In organic heart-disease chloralamid is safer and there is less danger and dread in giving it where there is any cardiac complication. Cervello claims that chloral injuriously affected the heart and that it created a difference from normal blood-pressure of from 50 to 80 mm., while chloralamid differed within the limits occurring during ordinary sleep 17 mm., so chloralamid, he infers, influences the heart but slightly.

Phenacetin, phenocoll, lactophenin and antipyrin are well known minor pain alleviators which incidentally and indirectly may cause sleep, but against each of these have been charges of their causing heart interference and cyanosis. Acetanilid of this series was regarded as the worst in this respect and antifebrin was presumed to be only a proprietary form of the former. Certainly pseudoscientific "headache-powders," extensively advertised, have here and there occasioned death; this has been laid to commercial impurities in the acetanilid. Reputable physicians are afraid to make too common use of such things, but the nostrum advertiser has neither fears nor scruples, an instance of ignorance and cupidity rushing in where knowledge fears to tread.

Conium maculatum was a favorite motor paralyzant in maniacal states, but is too dangerous for extensive use. Ergot is probably not used enough as an arteriole constringent where congestions produce pain or sleeplessness. Bromides are being dispensed more and to a reckless extent when their protracted use causes debility and poverty of blood. Cocaine is being abused in quack preparations, such as wines and catarrh snuffs. Both amylene hydrate and paraldehyde have suffocating odors and the latter has increased the number of epileptic fits. Hypnone, somnal and urethane have been practically discarded through unfavorable reports. The feebleness and unreliability of lactucarium shelves it as a curiosity more than a medicine.

Ernest Schultze[13] discusses the new mixture of chloral hydrate and amylene hydrate called Dormiol. It has a pungent menthol odor and burning taste. "Owing to its peculiar behavior in water" a ten-per-cent. solution in water is recommended for use. He says it failed in mania and paretic dementia and in the excitement of epilepsy. As the disagreeable properties of its components are not only retained by this new mixture and new ones added, while efficiency is lessened, its justification may well be questioned.

STATE SANATORIA FOR CONSUMPTIVES IN MICHIGAN.[1]

By HERBERT MAXON KING, M.D.,
OF GRAND RAPIDS, MICHIGAN.

QUOTING from a paper on the "Home Treatment of Consumption," read before the Medical and Chirurgical Faculty of Maryland last fall, Dr. Osler says: "For more than two centuries the clearer headed members of the profession have known that an open-air life sometimes cures a case of phthisis"; and, concluding, he says: "A rigid régime, a life of rules and regulations, a dominant will on the part of the doctor, willing obedience on the part of the patient and friends —these, with the conditions we have discussed, are necessary in the successful treatment of pulmonary tuberculosis." The "conditions discussed" are those toward which the efforts of every intelligent and experienced practitioner of medicine are directed in his management of the consumptive patient, whether in private or hospital practice.

It is unnecessary at this time to enter into any detailed description along the lines of the "open-air" treatment, the rigid discipline necessary in carrying it out successfully, or the supplementary medical treatment best to be employed. Suffice it to say that at the present time, all physicians of experience in the care of consumptives agree that the cure of the disease is the work of Nature; and that the chief function of the physician is that of a teacher, while his peculiar medical skill is devoted to the task of promoting nutrition and placing the economy in the most favorable condition to receive the benefits of the rational cure. Moreover, all are agreed that to be most successful treatment must be begun in the incipient stages of the disease, the so-called "pretubercular" stage which, as Dr. Trudeau and others have long maintained, is nothing in the world but the first stages of the tuberculous process before physical signs have appeared. Furthermore, that to effect a cure which will give the greatest security against relapse in this treacherous disease, treatment must be perseveringly continued, with untiring vigor, over a considerable period of time.

Upon these three points, then, there is such a unanimity of opinion that argument or citation of statistics are alike superfluous: (1) The "open-air" treatment systematically carried out, supplemented by such general medical treatment as the individual case may require is, up to the present, our most effective weapon against tuberculosis; (2) early diagnosis is essential to the best results, and (3) treatment to meet the highest requirements must extend over a considerable period of time.

When a patient is discovered in the early stages of tuberculosis, the question at once arises how best to fulfil these three conditions. When such a patient is from the wealthier class, or even from the less wealthy but well-to-do portion of the community, the chief difficulties which otherwise arise to embarrass the physician are at once overcome. A trained and specially instructed nurse, the Adirondacks, North or South Carolina, Colorado or California, settle the question; it is only the matter of details that demands further attention. But when the same disease appears in the family of the laboring-man, a class from which 90 to 95 per cent. of our consumptives come, most often attacking the bread-winner, the problem which confronts the physician is by no means as simple. Change from the environment in which the disease has developed is the first essential, and this, in most cases, means the cutting off of self-support. This compels the patient to assume, for an indefinite period, the rôle of a dependant at a time when it is not easy to convince either him or his friends that the trouble is of sufficient gravity to demand such radical measures. A trained attendant and travel or residence in a suitable climate under such conditions as best favor a cure are alike out of the question. The patient is seen for a few minutes perhaps once or twice a week and instructed in a vague sort of way in the care of the sputum, the desirability of a life out-of-doors, and such further hygienic and sanitary precautions as occur to the physician's mind at the time. Tonics are prescribed and a diet indicated, but all without any assurance that the importance of the situation is appreciated or that the directions will be followed as intended; in short, without that system and discipline which experience has for a century been teaching us are of such inestimable advantage in the treatment of consumption.

Institutional care for this appallingly large class of unfortunates is to-day recognized as the closest approach to the ideal treatment which modern social conditions make possible. Sanatoria for the treatment of the early stages of phthisis are no longer experiments. Wherever they have been established, whether by private endowment or State appropriation, they have more than met the most sanguine expectations of their supporters, yet the surprising fact remains that the vast majority of people, notwithstanding that one out of every forty or fifty of them is a consumptive, is supinely indifferent to the whole matter. However, perhaps this indifference is more apparent than real. I am convinced that once the medical profession expresses that unanimity of opinion which must follow a fair consideration of what has already been accomplished in this direction, there will be no further difficulty in securing the attention and interest of both legislature and people.

The pioneer efforts of Brehmer in Europe and Trudeau in this country have demonstrated beyond cavil the immense practical value of the sanatorium idea, not only as a means of curing the disease, but through its educational influence upon the community, both directly and through

[1] Part of the general discussion on the subject of Tuberculosis at the thirty-fifth annual meeting of the Michigan State Medical Society, at Mackinac Island, 1900.

the missionary work of cured and improved patients on their return to the work-a-day world, as an active preventative against the spread of tuberculosis.

There is already throughout the country a considerable agitation on the subject of State sanatoria. New York has recently appropriated the sum of fifty thousand dollars for the establishment of a sanatorium for incipient consumptives in the Adirondacks. Of course, this sum is absurdly small and can in itself effect very little, but it is a beginning in the right direction, and will no doubt be followed by more substantial appropriations in the near future.

In 1895 Massachusetts appropriated the sum of one hundred and fifty thousand dollars for the same object, and the State Hospital in Rutland is the result, a splendid institution of which the State may be justly proud. I am informed by Dr. Marclay, the superintendent in charge, that the plant as it now stands, with a full capacity of one hundred and seventy-five patients, cost the State about one hundred and seventy-five thousand dollars. As far as can be judged at present its first year's work ranks well up toward that which is yearly accomplished by Dr. Trudeau's Adirondack Cottage Sanitarium.

When once the current of public opinion sets in a certain direction it gathers force with every month and year, and while this question of State care of consumptives has been a long time gaining the force of public confidence, recent developments along the lines of the etiology and pathology of tuberculosis have produced their inevitable influence, and the medical sentiment to-day is so strong in favor of that which I advocate in this discussion that it is only a question of time, I am convinced when State sanatoria will be regarded as much an essential to the public welfare as is the school-house.

Without entering further into the general consideration of a subject so inexhaustible, let me briefly capitulate the points of chief importance to the condition of things respecting tuberculosis which confronts the Michigan practitioner to-day. As nearly as I can estimate from the statistics furnished by the State Board of Health and such information as I have obtained through the courtesy of its Secretary, Dr. Baker, there are in Michigan in the neighborhood of 1500 deaths per year from consumption. Probably this figure is too low by 10 per cent. to express the total number of deaths from all forms of tuberculosis. But allowing the number to be 1500, that would express perhaps three fourths of the number of new cases which develop each year within the state. If my estimate is correct, therefore, we have to consider: (1) That there develop in Michigan every year 2000 cases of tuberculosis. Of this number 10 per cent. are in such financial circumstances as to exclude them from present consideration. An additional 20 per cent. may be safely estimated to be unfit for sanatorium treatment by reason of the hopeless virulence of their disease, peculiar complications, or too long delayed diagnosis of their condition. Another 10 per cent. at least will leave the state for one cause or another. (2) This leaves us to consider that there are in Michigan about 1200 new cases of tuberculosis every year which are suitable for sanatorium treatment, and which under present conditions must be treated at their homes or at least within the state.

In the Massachusetts institution at Rutland the average stay at the hospital of those cases classed under "arrested" and "much improved" for the year ending October 1, 1899, was four months (see Third Annual Report of the Massachusetts Hospital for Consumptives, etc.). This, however, is too short a time for the attainment of the best results. In Dr. Trudeau's fifteen years' experience at the Adirondack Sanitarium, his best results were attained with an average stay of eight and three-quarter months ("Sanitarium Treatment of Incipient Pulmonary Tuberculosis and its Results," Medical News, June 2, 1900). In a state institution it would for obvious reasons be impossible to average so long a stay, even for the most favorable cases, and six months would be a generous estimate, while the unfavorable cases would be discharged very much sooner, as soon, indeed, as a fair trial had proved the futility of treatment. We have then to consider: (3) That sanatoria in Michigan with a combined capacity for 500 patients would fulfil our present requirements in this direction, allowing an average stay of four months to each patient.

As to cost. It has not been found practicable, either in Europe or in this country, to treat this class of patients in groups of more than 200. In Germany there are no institutions with a capacity greater than that, while, as before stated, the Massachusetts Hospital at Rutland has a maximum capacity of 175, and when recently there was a movement on foot to enlarge the buildings for the purpose of accommodating a larger number of patients, Dr. Bowditch and his associates strenuously opposed such a measure for reasons admittedly sound. It would, therefore, require three separate plants to fully meet the demand in Michigan. It would not, however, be necessary at first to ask for appropriation for more than one, since such innovations require practical demonstration of their usefulness to convince the people in general and the patients in particular that they do what is claimed for them. I judge that, with the advantage of the experience of Massachusetts and New York, we in Michigan might build and equip institutions which would be models of their kind, at a cost of $150,000 each. Then would follow the expense of maintaining them. Here again we may turn to the object lesson in Massachusetts. Dr. Marclay informs me that with full capacity the per capita expense of running that institution is $8.40 per week. Of this the patients pay a uniform rate of $4.00 per week, which leaves it necessary for the state to appropriate the balance. This plan of relieving such institutions from the

odium attaching to a purely "charity hospital" and the state from just so much expense, I should most certainly advocate, except that some provision should be made for allowing favorable cases to remain as long as necessary to effect most permanent results, even if they should be unable to continue paying the nominal rate charged.

In this connection Dr. Trudeau, whose long and successful experience adds weight to his advice, writes me as follows: "It seems to me that if you could get an appropriation of $8.00 per week for each patient, with care it might be run on that basis. From my experience I would say that the whole success of the thing will depend on two things; first of all, the class of patients you admit, and the obtaining of incipient cases is surrounded with difficulty. Secondly, the manner in which the institution is run and controlled, and the site which it occupies." And it seems to me that right there is the gist of the whole expense question. If we can be assured of a good management and can keep our proposed sanatoria free from "pot-house" politics we can promise the state that the necessary appropriations, after the initial cost of construction and equipment is met, will be comparatively insignificant.

Before concluding let me for a moment point out the feasibility of the establishment of state sanatoria for consumptives in Michigan.

First, as to the mooted question of climatic influence in tuberculosis. That Michigan does not furnish the most salubrious climate in the world, I will not deny; indeed, I am ready to agree that, all other conditions being identical, a consumptive might do better in any one of several other localities; but I also contend that the chief advantage thus derived would lie in the greater number of hours of sunshine to be enjoyed out of doors and not in the high altitude and rarefied air. The elevation of the Massachusetts Hospital at Rutland is 1200 feet above sea level. This is obtainable in many Michigan localities. Hillsdale County, for instance, the highest elevation south of the Grand Saginaw valley, is about 1200 feet. The Adirondack Cottage Sanitarium is situated at an elevation of about 1600 feet. This height can be obtained in Michigan in the northern portion of the southern peninsula, notably in Antrim and Otsego Counties, where a gently-rolling, well-wooded and magnificently-watered plateau reaches in several culminating rises an elevation of nearly 1800 feet above sea level. Moreover, other climatic conditions obtainable in Michigan are at least equal in healthfulness to those at Rutland and not much inferior, heretical as it may seem, to the Adirondack region. I think it safe to say that in properly managed sanatoria, suitably located, and officered by men selected for their professional ability alone, irrespective of political considerations, we might expect fully as large percentages of "apparently cured," "disease arrested" and "much improved" in Michigan as are reported from any institution of the kind in the world.

In any event, we must remember that the class of patients which we are considering must of necessity be treated and cared for in Michigan, whatever may be the disadvantages of its climate. And admitting that the "open-air sanatorium treatment" not only offers to these patients the best chances for recovery, but is a most potent factor in preventing the spread of the disease. That such institutions as are asked for, with their maintenance, are reasonably within the financial competency of the state, I think we must all agree; also that the establishment of such institutions would be a perfectly feasible measure and one which if adopted would yield amply satisfactory returns to the people of the state.

At first I would advocate the securing of an appropriation for but one plant, to be situated in a locality reasonably accessible to the larger cities of Michigan, such locality to be selected for its peculiar fitness for the purposes intended, by a commission also selected for the special fitness of its members for the work intrusted to it.

Such an institution should, in my opinion, be officered by a "visiting staff" of not more than four physicians, who should be appointed by reason of their professional experience and ability, who should have quarterly terms of service, without remuneration, and who should govern not only the treatment of the patients but the selection of suitable cases for the sanatorium and have immediate supervision of the "resident staff" which should, of course, be salaried.

This subject is one which can receive but a very small part of the attention which its importance merits in any limited discussion, but it is one which we certainly owe it to ourselves and to the community in which we live to give our most thorough consideration. And to that end I shall at the proper time offer a resolution at this meeting of our Society for the appointment of a special committee whose duty it shall be to bring the matter properly before our next legislature.

I am aware that the subject has before been exploited at previous meetings of our legislature, but never before with so much to offer in demonstration of its importance or the success which has attended recent movements of the sort in other states, and in the present case I am sure that the voice of the sentiment of this Society is that of one man; and if I am right in so thinking the eventual realization of the idea is certain.

A STUDY OF DRAINAGE.

By A. M. POND, M.D.,
of Webster City, Iowa.

I purpose to show in this paper that drainage, so far from being the necessity it was once believed, is of value in comparatively few cases, and in others is a positive detriment. Before passing to a direct discussion of the topic, however, I wish to consider some features of the

pathology of the blood and wounds in general.

In wounds with an external solution of continuity an abundance of blood serum is deposited immediately upon injury in and about the injured surface. This serum is of itself an antiseptic, inasmuch as it agglutinates apposing tissue and by so doing resists invasion of foreign and toxic elements that would endanger the function of repair.

Fortunately this serum is insoluble except in a weak solution of salt and water, so that repeated washings do not deprive the injured tissues of their protection without which suppuration would be the invariable result. I believe that the medical world now is unanimous in asserting that any wound, free of infection, heals spontaneously without any of the elements of inflammation and especially without pus.

This brings us to a consideration of the process known as chemotaxis, the faculty possessed by all motile bacteria of moving toward or away from certain substances according as those substances attract or repel them. This motility is also possessed by leucocytes and other plasmodiæ. Bacteria move toward any material that furnishes them nutriment, hence bacteria have an affinity for leucocytes and leucocytes an equal affinity for bacteria. The leucocyte acts the rôle of a natural scavenger and responds promptly to chemotactic attraction upon introduction of foreign, dead or offending material, by enveloping or appropriating such substance and removing it. Thus bacteria and leucocytes being mutually attractive, although the function of one is to destroy while the office of the other is to preserve, are forces arrayed against each other, and it is simply a question of resistance and physical perfection whether an injury is protected by leucocytes and goes on to complete repair without interruption, or suffers loss and delay by the energetic attempt of the bacteria.

Blood-serum consists of proteid material, which in suppuration first attracts the bacteria, and leucocytes, which oppose them. The pus is composed of leucocytes which have perished in the struggle.

Of the class of injuries in which there is no solution of continuity, such as abscesses, intra-abdominal and others, the process of repair is the same as that above described, infection taking place from invasion of bacteria through the colon, uterus, tubes, tonsils, lymphoid structures and other recognized avenues.

It is apparent that one seldom if ever sees infection about a simple fracture, because its location is removed from any avenue of entrance for bacteria. The process of repair is therefore not attended by inflammation, but consists of hyperemia or determination of the blood-cells accompanied by dilation of the blood-vessels. Stagnation of the blood-current and the pressure produced by the vast number of blood-cells cause pain by pressing on the nerves, but, as soon as the circulatory disturbances subside, the pain ceases, the congestion and hyperemia disappear, and no pus is formed.

In any injury infection may, of course, be favored by certain physical conditions, such as already existing toxemia, anatomical changes which lower vitality, variation of nutrition, and unhygienic surroundings. There is also good reason for believing that prolonged anesthesia, by lowering the arterial pressure and limiting the amount of oxygen inhaled during a long operation, may produce such changes in blood and tissue as to interfere seriously with the necessary processes of repair and chemotaxis and thus facilitate infection. Even antiseptics, if employed too lavishly may, I believe, favor infection by poisoning the leucocytes and checking their action on the bacteria.

In addition to the conditions mentioned above infection may result from imperfect sterilization, whether of the skin and hair of patient and operator, which is indeed difficult of attainment, or of the instruments, gauge, suturing material, etc., used in the operation.

Having hinted at the action of the chemotaxis in the formation of pus and at the physiological protection afforded by the blood-serum and having also reviewed the forces causing infection and thus creating a demand for drainage, we are now prepared to consider the specific subject of this paper.

Drainage was first used to remove the pus which was the inevitable concomitant of surgery before the present era of asepsis and antisepsis. Drainage was then considered, and justly, a necessity, since without it absorption of poisonous material was inevitable.

Latterly we have drained to prevent pus formation, a process to my mind essentially unscientific. In a recent text-book occurs the expression, "Drainage empties the surface of blood-serum." So it does, but why do we want to empty the surfaces of the blood-serum, since, as we have seen, the serum acts as an antiseptic, occluding all dead spaces and promoting repair? Furthermore, the very presence of the drain, no matter how sterile the gauze may be, excites by irritation an increased amount of serum and the formation of blood clot; the excessive serum is then drawn by capillary attraction throughout the extent of the drain until all is moistened, creating a direct communication from a sterile wound cavity to an intensely infected atmosphere, providing a highway, if you please, for infection, at one end of which is blood-clot, an ideal culture medium for bacteria, at the other end myriads of bacteria anxious to be cultured. In the same text-book referred to above we find this statement, "The function of the gauze is complete after a few hours and may be removed." But its presence during even the few hours has altered cell-activity by its irritating action, and after its removal more serum must be formed that will protect the injured surfaces, fill up the dead spaces and promote restoration.

In certain of the septic and infective cases we must, of course, continue to drain, thereby sustaining the position of the older men who drained because they knew pus would form, as we now drain because we know pus *has* formed. I purposely state that we must still continue to drain some of the septic cases, for I want to be emphatically understood that I believe many of our septic cases can be made sterile and the wound closed without drainage.

In abdominal surgery the same general rule remains applicable, but here we also have other means of combating infection, *viz.*, purgation. It has been demonstrated beyond dispute that anything which interferes with the absorbability predisposes to infection. This is doubly true of the peritoneum, and free purgation promotes absorption by lessening the stasis of intestinal and peritoneal vessels.

Waterhouse has given us many interesting statements of experiments concerning the relations of blood-elements and toxins. He injected 6 c.c. of a cloudy culture of staphylococcus aureus into the peritoneal cavity of dogs without serious results; he then injected 8 c.c. of urine and small amounts of blood, likewise without serious results. Finally, he injected blood-clots and small amounts of a culture of staphylococcus aureus, resulting in a rapidly-developing peritonitis and death in twenty-four hours. This certainly should teach us that we must protect the blood-clots from invasion by bacteria, and the question arises, Can we do this by drainage? There is a fixed relation existing between the power of absorption of the peritoneum and the possibilities of infection. It has been positively proved that the peritoneum not only can, but does, dispose of large amounts of pyogenetic material as long as its absorbability is not interfered with; the less absorption the greater the danger, hence anything tending toward irritation of the peritoneum, promoting stasis of its vessels and retarding absorption, is a source of danger. Is, therefore, a foreign body like a drain tolerated by the peritoneum any more than any other irritant?

By diluting infection we promote absorption. The peritoneum can take care of a weakened solution of infectious material much more easily than it can make immune a surface constantly producing sepsis. A salt solution may be useful here, inasmuch as it is solvent to blood-clots, is itself a physiological fluid, and is very readily absorbed by the peritoneum and intestines, experiments showing that the normal peritoneum is capable of absorbing from three to eight per cent. of the body weight in one hour and the entire weight of the body in twenty-four hours. In its altered state, as produced by disease, we cannot say how much fluid it is able to absorb; we do know, however, how to stimulate the absorbability even of a diseased peritoneum.

Many unfortunate sequelæ follow in the wake of abdominal drainage. Hernia is common and may be said to be caused by drainage, the presence of which through the layers of the abdominal wall has lessened the cell-activity and weakened the repair. No other cause of ileus is so common, and removal of the gauze drain, when the tender granulations have grown through the meshes of the drain and are rudely torn, causes intense pain and sometimes serious relapse. We have seen that blood-serum plays an important part in the repair of wounds; that chemotaxis bears an important relation to pus formation, and that, *in sterile cases,* drainage is not only unnecessary but positively detrimental. Let me, therefore, urge upon you that, having given the patient the benefit of scrupulous care directed toward securing perfect sterilization, you restrict the use of drainage to those cases in which all the means at your disposal fail to render aseptic and non-infective.

CLINICAL MEMORANDUM.

A NEW URETHROTOME.

By GEORGE RUBIN, M.D.,
of Chicago, Illinois.

This urethrotome consists of three separate parts, *viz.*, a grooved shaft with bulb, a knife and a filiform (Guyon) conductor.

The grooved shaft is of small caliber, having at its lower end an olive-shaped bulb which conceals the blade. The lower third of the shaft is flexible; it bends either forward or backward, according to the manner in which it is to be used. At the upper end of the shaft are placed two fine screws which serve to arrest the blade within the bulb. When both screws are closed, the knife is fixed in the bulb and the instrument may be used as an exploratory sound without the least danger of injuring the urethra. When cutting forward, the right screw is closed and the left one opened, and after the incision is made, the knife is pulled back into the bulb, where it is automatically arrested. The operator, after each incision, will draw in the knife and try to pass the bulb; if the bulb does not go through, the instrument is turned a little to one side and another incision is made. If it still does not pass, the instrument should be turned around to the opposite side, and then posteriorly, etc., until the surgeon is able to pass the bulb with comparative freedom, because if the passage of the bulb is interfered with or requires some force to pass, it would show that not all the bands of cicatricial tissue have been severed.

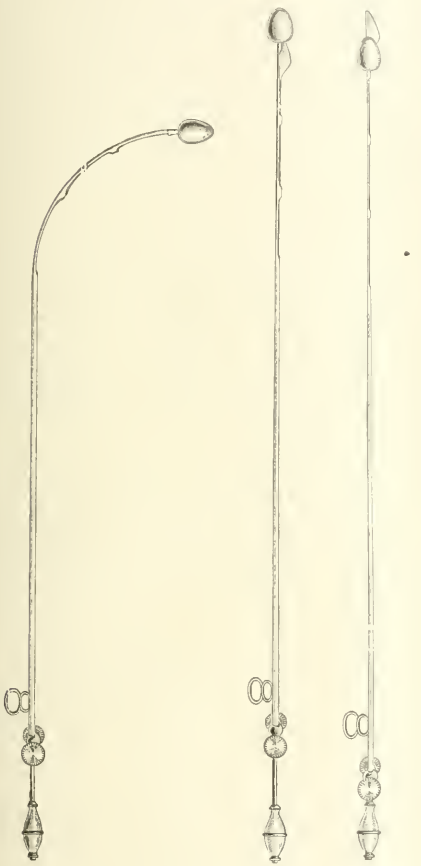
The knife is mounted on a very slender, flexible steel shaft, like the Maisonneuve, but the knife is not like Maisonneuve's, as the sharp edge extends over its whole convexity.

The conductor is a woven-fabric filiform bougie like Guyon's conductor, with a screw by which it can be connected to the apex of the bulb.

The filiform bougie serves as a guide and always directs the blade to the center of the lumen.

The urethrotome is most simple in construction and very easy to manipulate, and it is a very safe instrument in the hands of a non-specialist.

Fig. 1.



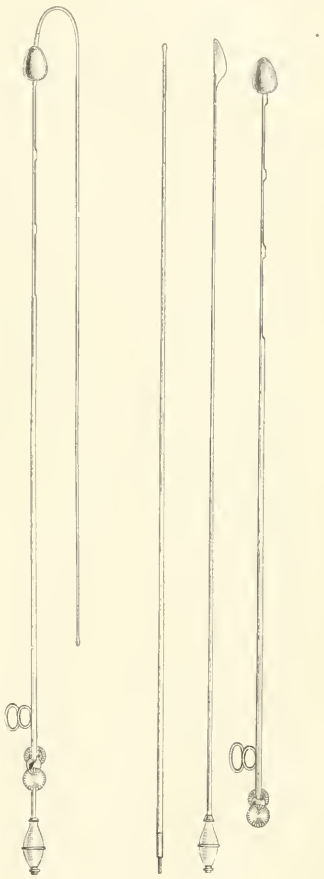
New Urethrotome.

All the parts are separate and uncomplicated and it is therefore easy to render them aseptic.

It is the only urethrotome with a bulbous end where the knife comes out in front of the bulb. The bulb keeps the healthy portion of the urethra distended and exposes the constricted portion to the knife; in this way it does not matter how narrow or how wide the stricture may be, the results will be practically the same. To cut a stricture of very large caliber, the bulb is passed beyond the stricture, and on the attempt to withdraw the bulb the stricture will naturally resist, so the bulb is retained in place and the knife is drawn backward, and if it still resists one proceeds in a similar manner as cutting forward and as many incisions are made in the circle as are necessary to permit the passage of the bulb without the least resistance.

By closing the left screw and opening the right one the knife will be arrested when its whole length is out, and when it is pushed back it will be again concealed within the bulb. Another and an entirely new feature of the urethrotome is its flexibility which is more than is necessary to accommodate the curve of the urethra.

Fig. 2.



New Urethrotome and Stylet.

Two urethrotomes—one with a bulb No. 27, and another No. 23, metric scale—ought to be sufficient for all practical purposes, the former

being of the average size of a normal urethra (adult), and the latter suitable for patients with abnormally narrow urethras or in cases of young adults.

When internal urethrotomy is decided upon, I believe it is best to at once reestablish the constricted portion to its normal caliber, and thus save ultimate lacerating with sounds in the after-treatment.

The instrument is made at the present time by Collin, Paris, and Truax, Greene & Co., Chicago.

MEDICAL PROGRESS.

Meningococcus Intracellularis.—According to the experiments of Jaeger and Weichselbaum, writes Louis Fischer (*Pediatrics,* Oct. 15, 1900), this organism is far less virulent than the pneumococcus, bacterium coli, or the influenza bacillus, as shown by the frequent recovery from epidemic cerebrospinal meningitis, and the fatality of the other forms. The one constant symptom is spasm of the neck muscles which disappears only during convalescence, and is often absent in tuberculous meningitis. The best method of differentiation is by lumbar puncture and staining a smear from the pure culture on agar with Ziehl's solution. The tube-growth is rapid, yellowish, shiny, and slimy. Tapping the spinal canal has not only aided the author in diagnosis, but has given temporary or even permanent relief of the symptoms.

Nutritive Enemata and Gastric Secretion.—L. Metzger (*Münch. med. Woch.,* Nov. 6, 1900) has introduced various substances into the rectum of dogs and human beings in order to determine whether a flow of gastric juice took place. The experiments have in the main been negative with milk, eggs and other foods. If, however, red wine was added to the clyster, free hydrochloric acid appeared after a short latent period. The stomach-contents usually remained acid to litmus for an hour. The cause for the peculiar action of wine is not quite clear, but probably depends upon a reflex excitation.

Exploratory Craniotomy.—A new instrument is described by A. Codivilla (*Revue de Chir.,* Nov., 1900) for opening the skull, designed to replace largely the set of trephines and to cut out circles of bone larger than they make possible. Its parts are a tripod sharp-pointed center, transfixed vertically and centrally by a screw which passes through the skull and forces the points of the tripod into the outer table. Upon this center revolves a sleeve which carries the handle, hinged horizontally upon it. The handle presents a longitudinal slot, with a graduated scale along its upper face. In this slot plays the cutter-carrier which has thumb screws for setting it at any point of the scale and for advancing the depth of the cut into the bone. With the center *in situ* and the blade placed, the handle is carried round the pivot under manual pressure till the tables are divided when instrument and bone-button are removed together. The recapitulated advantages of this device are (1) the formation of any bone-flap which can be composed of segments of a circle; (2) division of the soft parts in the same geometrical form as the bone, but larger; (3) linear incision of the bone with little sacrifice of its tissue; (4) rapid, certain action without danger of damaging the cranial contents; (5) ease of assemblage application, operation and sterilization; (6) inexpensiveness.

The Kidneys and Glycosuria.—Certain indications, according to F. P. Rechter (*Zeitschrift f. klin. Med.,* Bd. 41, Hft. 1-4), seem to show that disease of the kidneys in diabetes can render the excretion of sugar difficult, leading to an apparent cure. It is also difficult to cause alimentary glycosuria in nephritis and in the same manner phloridzin is unable to cause much excretion of sugar in animals in which a nephritis has been artificially induced. The author thinks that the activity of the kidneys is an important factor in diabetes.

New Tissue in Cirrhosis of the Liver.—Simon Flexner (*Univ. Med. Mag.,* Nov., 1900) discusses at some length the nature and distribution of the new tissue in cirrhosis of the liver, and from his studies has drawn the following conclusions: (1) In all forms of cirrhosis the white fibrous tissue is increased. (2) Along with the increase of white fibrous tissue there is a new formation of elastic tissue. This new elastic tissue is derived from preexisting tissue in the adventitia of blood-vessels and the hepatic capsules. (3) Both white fibrous tissue and elastic tissue, in all forms of cirrhosis, may penetrate into the lobules. This penetration takes place along the line of capillary walls or follows the architecture of the reticulum. The chief distinctions between the histology of atrophic and hypertrophic cirrhosis depends upon the degree of extralobular growth and the freedom with which the lobules are invaded. In hypertrophic cirrhosis there would appear to be less interlobular growth and an earlier and finer intralobular growth. (4) The alterations in the reticulum, *per se,* consist, as far as can be made out at present, of hypertrophy rather than hyperplasia of the fibers. It is still uncertain whether any of the differential methods now in use suffice to distinguish between the reticulum and certain fibers derived from the white fibrous tissue of the periphery of the lobules.

Absorption and Metabolism in Apepsia Gastrica.—In a series of cases of apepsia or achylia gastrica, F. Strauss (*Zeitschrift f. klin. Med.,* Bd. 41, Hft. 1-4) has found the absorptive powers

of the gastric mucous membrane unchanged. Even in the intestines the food is utilized to almost the same degree as in health provided diarrhea was not present. Experiments with metabolism did not indicate that any pathological destruction of albumin occurred and the toxicity of the urine was remarkably low. Cases suffering from pernicious anemia gave the same results, which seems to speak strongly against inanition or intoxication as a cause for the anemia.

Justus Test in Syphilis.—The so-called "Justus test" is based upon the following proposition: Mercury destroys the hemoglobin of the blood. In the non-syphilitic subject, the organism rapidly replaces the lost pigment. In the syphilitic patient, however, the percentage being reduced by the disease, the organism cannot at once restore the still further reduction caused by the use of mercury. Consequently the first examination after an inunction or injection of mercury will show a distinct fall of from 10 to 20 per cent. This reduction is in turn followed as treatment is continued by a steady rise to the normal, where it remains so long as treatment is continued. Based upon their application of the test in 29 cases and their study of it as to its diagnostic value H. M. Christian and Otto H. Foerster (*Univ. Med. Mag.*, Nov., 1900) have arrived at the following conclusions: (1) That in the diagnosis of doubtful ulcers it is of no value. (2) That it seems to occur in a certain proportion of cases of acute secondary syphilis, where it appears to be a symptom of the disease and can in no sense be considered a true test, as the diagnosis in such cases is already complete. (3) That as a test it is not reliable, occurring as it does in conditions other than syphilis.

Idiopathic Phlegmonous Gastritis.—This disease is so rare and the number of cases reported so small that F. P. Kinnicutt (*Phila. Med. Jour.*, Nov. 17, 1900) reports a case which is one of two only of this form which he has seen in a good many years. The patient was a plumber, forty-one years of age. He had never had trouble with his stomach except after excessive drinking. After a hearty meal following a period of heavy drinking he began to vomit. At first the vomited matter consisted of food and later of a brownish fluid. The vomiting occurred frequently for four days irrespective of the taking of food. He had slight diarrhea. There was not any blood in the vomited matter or the stools. Some acute and more or less constant pain was present in the epigastrium and in the lower abdomen. The patient's pulse was 108, temperature (rectal) 101° F., and respiration shallow and 48 to the minute. The patient was anxious, restless, and undoubtedly very ill. Physical examination showed chiefly that the abdomen was moderately distended, with considerable rigidity of the abdominal walls, especially in the upper half. Slight sensitiveness on palpation was present, most marked over the epigastrium and the right hypochondrium. Slight crepitation was heard over the liver region and over the left hypochondrium. There were no signs of free fluid in the peritoneal cavity. Abdominal respiration, though present, was diminished. Urine, specific gravity 1025, was negative except for a few hyalin and granular casts. Lavage was employed and an odorless yellowish-brown fluid was returned. A general peritonitis was believed to exist, the supposed cause being an acute pancreatitis or a perforating ulcer of the duodenum. Preparations were made for an exploratory laparotomy, when the patient rapidly failed and died. He vomited large quantities of the yellowish-brown fluid during his last hours. Autopsy showed a diffuse suppurative gastritis and general peritonitis. There was a moderate amount of turbid fluid in the peritoneal cavity with some adherent fibrinous exudate. The walls of the stomach, which was normal in size, were greatly thickened due to a purulent infiltration of the submucosa. This thickening amounted to fully an inch at the pylorus and for three inches around it. The lower end of the gullet showed the same thickening and infiltration. The changes found in the stomach walls were swelling, softening, intense cellular infiltration, and a countless number of micro-organisms. The bacterial examination showed the universal presence of a streptococcus.

Apparent Tumors of the Abdomen.—Abdominal diagnosis is frequently a very difficult problem and eminent men have often said that they are seldom sure of the internal condition, after an external examination, even in comparatively simple cases. Max Einhorn (*Med. Rec.*, Nov. 24, 1900) says that he has had 42 cases of apparent tumor out of a total number of 6045 cases. These were instances of a mass in the upper part of the abdomen which could easily be mistaken for a neoplasm. He believes that they may be due to the following causes: (1) Prolapse of the left lobe of the liver; (2) exposure and thickening of the abdominal aorta; (3) hypertrophic condition of the abdominal muscles; (4) adhesions around the small curvature of the stomach. As no autopsies were performed his opinions are based entirely upon clinical examinations. In apparent tumors the mass presents a more or less smooth surface, with no distinct nodules. It is not always felt with the same ease and may even disappear altogether. A high degree of enteroptosis is usually associated with it. It may occur at any age; the history usually extends over a period of several years, and malnutrition is very gradual. The differentiation from malignant tumors is, however, very difficult at times and may be impossible.

Treatment of Cholelithiasis.—K. Witthauer (*Münch. med. Woch.*, Oct. 23, 1900) thinks that gall-stone operations are done too frequently at present and recommends that where fever and

enlarged gall-bladder are absent surgical interference should be deferred until medical treatment has been given a fair trial. The treatment at Carlsbad no doubt is best, and after this the administration of olive oil. This is first to be tried by mouth, with peppermint oil as corrigent, and only when the repugnance toward oil is great may it be given per rectum. Although this method is considered by many as antiquated, the author has found it necessary to advise operation only 5 or 6 times during his experience.

Cardiac Wounds.—Three recoveries among eleven cases of wound and suture of the heart in literature have been collected by F. Ferrier and E. Raymond (*Revue de Chir.*, Oct., 1900). The following conclusions have been reached: (1) The best flap for abscess is a thoracic trap-door with the hinge outward. (2) It is best not to open the pericardium across the pleura, but to carefully push this aside laterally. (3) Interrupted sutures are as a rule best for the cardiac wound itself. (4) In the majority of cases a drain is not needed for either the pericardium or the pleura.

Etiology of Eczema.—The predisposing causes of eczema are so numerous and diverse that the theory is frequently advanced that this may be an instance in which a single name is given to several distinct and separate conditions. L. D. Bulkley (*N. Y. Med. Jour.*, Nov. 17 and 24, 1900) has given a complete résumé of the multitudinous predisposing and exciting causes and is inclined to agree with Brocq that "eczema is the image itself of the life, the reflex on the skin of the constitution of the individual." The parasitic theory of causation was fully discussed at the International Congress last summer and the results may be summed up as follows: The majority of dermatologists do not regard eczema as a parasitic disease, due to a specific organism. The micrococcus of Unna is almost universally regarded as an ordinary staphylococcus with a slight peculiarity in its growth. Many observers are convinced of a local predisposition to eczema in the seborrheic state and a general predisposition in the circulation of various toxins in the skin, from the improper assimilation of food and other toxin-producing pathological conditions.

Atropine in Intestinal Obstruction.—That cases of acute intestinal obstruction, where immediate operation seems the only hope, sometimes are cured by large doses of atropine is evident from the case cited by B. Marcinowski (*Münch. med. Woch.*, Oct. 23, 1900). When first seen the patient was in collapse, with extremely tender abdomen, tympanites and vomiting. The following evening, after the vomitus had already become feculent, ½ of a grain of atropine was injected with the result that the absolute constipation was relieved and that the collapse symptoms slowly disappeared. After fourteen days the patient was up and about. An equally perfect result was obtained with the same large dose of atropine in a case of incarcerated hernia which had already been prepared for operation.

Intestinal Rupture.—J. J. Buchanan (*Annals of Surgery*, Nov., 1900) submits a case of traumatic rupture of the intestines with operation and recovery. The following are the points of interest; (1) Extensive peritonitis and free exudate within six hours after the injury; (2) rupture of the intestine without sign of external injury by an apparently slight blow; (3) almost entire absence of symptoms except failure of peristalsis and slight vomiting; (4) apparently favorable effect of Fowler's posture in the after-treatment; (5) entire adequacy of a long glass tube drain down to the pelvis, cleaned every half hour for the first day and at longer and longer intervals for the first four days.

Malaria.—J. McFarland (*N. Y. Med. Jour.*, Nov. 17, 1900) reviews the knowledge of malaria and shows the important advances made since 1880, *viz.*, the discovery of the plasmodium by Laveran, the discovery of its developmental cycle in man by Golgi, and its developmental cycle in the mosquito by Ross. The proofs are now complete that it is the *Anopheles claviger* which carries the organism from man to man. After sucking the infected blood from a human being, the mosquito harbors the parasites which undergo a cycle of development in about three weeks, and minute embryo-parasites are formed which are excreted in the saliva. To be infected with malaria, therefore, it is necessary to be bitten by a certain kind of mosquito at a definite time after it has been infected by the blood of a malarial patient. It is not the bite which causes the trouble, but the presence of the embryo-parasites in the saliva of the mosquito.

Puerperal Fever.—The usual treatment of this lamentable condition in the Bürgerspital, Hagenau, says Victor Steiner (*Centralbl. f. Gynek.*, Nov. 3, 1900) is as follows: Local disinfection of the vagina is striven for by copious lysol douches, 1-to-1000; after this the uterus is freely irrigated with kresol, half of one per cent., through the largest obtainable male catheter. Kresol is not only powerfully antiseptic, but relatively non-toxic, and in solution is clear so that blood-clots, fragments of placenta and shreds of membrane may be easily perceived in it. Extension of the inflammation into the pelvis demands cold locally. Quinine in large dose is used to combat chills due to the intra-uterine douches. Absolute quiet and perfect regulation of the bowels are absolutely necessary. Opium is often indicated, but may constipate, a fact often causing rise in the temperature. Serumtherapy has not been very successful.

Delirium Tremens.—The necessity of quieting a patient suffering from alcoholic delirium is easily appreciated, but it is oftentimes found a most difficult task even after large and frequent

doses of narcotics have been used. Good results have recently been reported from large doses of digitalis used especially at Bellevue. C. J. Douglas (*N. Y. Med Jour.*, Nov. 17, 1900) after considerable experience again urges the efficacy of apomorphine hypodermatically in doses of 1/30 of a grain. He says that the stream of consciousness can be shut off with valve-like precision by this method. Patients should not be restrained by physical force. It is needless and ineffective. Alcohol in some form should be prescribed, as its sudden withdrawal aggravates the disease and sometimes causes it. They should be nourished with milk, egg-nog or some other liquid food. The apomorphine acts within five or ten minutes and lasts from four to five hours. It may then be repeated. It seldom causes nausea.

Some Experiences with Fersan.—It is well known that, in giving iron in inorganic form, one must give much larger doses than are actually utilized and that gastro-intestinal disorders are almost invariable concomitants. The latter is also true of many organic preparations, not a few of which are unable to improve the composition of the blood. J. E. Folkel (*Münch. med. Woch.*, Oct. 30, 1900) speaks well of fersan, an acid albumin obtained from the red blood-cells. Not only as a blood tonic does fersan rank high, but as albuminous food it is only excelled, among the newer preparations, by plasmon. Special advantages are the high percentage of phosphorus which the drug contains, the entire absence of gastric disturbances, even after long use, and the rapidity with which the impoverished blood reaches the normal. Neither phthisis nor nephritis are contraindications to its use.

Eucaine in Medullary Narcosis.—To ascertain whether eucaine B would be an advantage over cocaine in spinal cocainization F. Engelman (*Münch. med. Woch.*, Oct. 30, 1900) had 1/6 of a grain injected into his subarachnoid space. After half an hour wandering pains were noticed in the small of the back which became intensified during the next hour, so that sitting on a chair was impossible. About the same time nausea, followed by protracted and severe vomiting, occurred and soon 8-10 chills and severe headache. On assuming the recumbent position the lumbar pains diminished, but the headache became almost unendurable and was coupled with an attack of dyspnea, excitement and precordial pain. The following day the pains persisted and even during the next week occasional neuralgias reminded the author of the experiment. It is noteworthy that not the slightest trace of anesthesia, even in the lower extremity, was present.

Thyroid in Cretinism.—J. H. Musser (*Internat. Med. Mag.*, Nov., 1900) reports several cases which appear to be on the borderlands of cretinism. Many of the features of these cases were lacking so that the diagnosis might be overlooked. Mental deficiency seemed to be the more prominent symptom in these patients. They were trained with the greatest difficulty and their personal habits were usually very uncleanly. Fits of temper, fretfulness and peevishness were common. Some of them showed a few characteristic features of this disease, especially in the development and contour of the face. The thyroid extract was very efficient in all these cases.

Functionating Power of Kidney After Nephrectomy.—Catheterizing the ureters in renal cases has been an enormous advance in surgery. It discloses the presence of a second organ and, to a certain extent, its functional value. There are many cases, however, where this method fails, as, for instance, where, usually owing to a tuberculous process, the bladder has so changed its shape that it is impossible to find the ureteral orifices. In such cases resort may be had to the following methods, according to H. Kummell (*Münch. med. Woch.*, Oct. 30, 1900): (1) The determination of urea. (2) The determination of the freezing-point of the blood. (3) The determination of the freezing-point of the urine. (4) The administration of methylene blue or phloridzin with subsequent examination of the urine. The first method is undoubtedly the simplest, but is the least trustworthy owing to the marked normal variations in the amount of urea excreted. Yet it may be said that a reduction down to 15-16 grams daily indicates insufficiency. A much more accurate method is the second. It has been found that normal blood has a freezing-point 0.56° C. below that of distilled water. A diminution of the freezing-point down to 0.50° C. or lower indicated in all cases that the kidneys are not functionating properly and contraindicates operation. Instead of blood, urine may be tested, when a freezing-point of minus 0.9° C. indicates renal insufficiency. This, however, does not hold true so absolutely as in case of blood. By means of a special apparatus the seemingly difficult experiment is rendered very simple. Cryoscopy, this new method of determining the functional quality of the kidney, promises to give some important results.

Extract of Testicle in Tabes.—The glowing reports which were made by Brown-Séquard upon the beneficial effects of this animal extract, especially upon himself, a man of seventy-two, has led to further investigation in many diseases. Tabes dorsalis and sclerotic diseases of the spinal cord are the conditions which have been most frequently treated by this drug. D. J. McCarthy (*Internat. Med. Mag.*, Nov., 1900) finds that even when the disease is rather far advanced there is often a certain amount of stimulation, the tone of the pulse becomes better, and the sexual hope of the patient may be resurrected by emissions and erections. There is, also, an increase in weight and nutrition usually following this mode of treatment; but the effect proves to be only an amelioration of the symptoms.

THERAPEUTIC HINTS.

Diphtheria.—Antitoxin treatment should be undertaken in every case and with all haste, writes Gilman Thompson. The patient's room should be kept at temperature of 68° F. with a tea-kettle or croup-kettle to render the air moist, or the steam may be directed under a tent improvised over the patient. The diet may be milk, broths, gruels, meat juice, egg albumin, oatmeal or barley-water, and ice cream. If swallowing is difficult peptonized milk and white of egg should be given every five hours. Thirst demands water and cracked ice. A temperature of 103° F. may require sponge baths at 80° F. The medicinal treatment consists of the following:

℞ Tinct. ferri chlorid. 0.7-2.0 (♏ x-xxx)
Glycerin..... .....
Aquæ .....aa. 8.0 (℥ ij)

every three hours, and mercury bichloride, gram 0.001 (gr. 1/60), q. 2 h., for a child of two years. For failing heart brandy is the best stimulant, with digitalis or strychnine, gram 0.0005 (gr. 1/120). The local treatment is chiefly directed to cleansing the mouth and nose. Irrigations are best and may be given with the child laid horizontally on a table, the head low, and the mouth directed toward the edge. The solutions best adapted for irrigation are: (1) Carbolic acid 3, alcohol 30, and water 70 parts; (2) bichloride of mercury 1 to 2000, with 4 or 5 parts of tartaric acid; (3) peroxide of hydrogen; (4) 1-per-cent. creolin; (5) Löffler's solution, which consists of:

℞ Menthol..... ..... 10.0 (℥ iiss)
Toluol q. s.....ad. 36.0 (℥ ix)
Liq. ferri chloridi..... 4.0 (℥ j)
Alcoh. absol..... 60.0 (℥ ij)

All irrigations are lukewarm, never forceful, and may be used every two or three hours, or every hour in severe cases. For nasal use the above must be diluted. For a laryngeal membrane syrup of ipecac, one or two teaspoonfuls, or mercury subsulphate, gram 0.12 (gr. ij), may be employed early, or, better, calomel, gram 0.7 (gr. x), may be vaporized on a tin dish and inhaled.—*Practical Medicine.*

Chronic Catarrhal Colitis.—Treat, not only the colitis, but rather the general physical condition, flatulence, nervous symptoms, etc., says Delafield, and do not look at the feces too often lest the patient's mind dwell too much upon them. Give plenty of mixed diet, noting the effect of special foods. Advise plenty of fresh air and exercise, and horseback or bicycle riding. Keep men at business. If constipated give the mildest laxatives; if there is diarrhea the bismuth preparations are harmless and please the patient. The routine medication consists of capsules of castor oil, gram 0.3 (♏ v), and salol, gram 0.3 (gr. v), or cubebs, gram 0.3-0.7 (gr. v-x), acid arsenous, gram 0.002 (gr. 1/30), and belladonna up to the poison limit. When only the rectum is involved, irrigate every day for a month with mild zinc-sulphate or zinc-chloride solution, or with infusion of linseed, and give no drugs by mouth. In the prolonged cases a dry, inland, elevated climate may be beneficial. Here the patients should be encouraged to live in the open air most of the time.

Simple Conjunctivitis.—Examine first, says De Schweinitz, for foreign bodies or misplaced cilia. In the earlier stages cold compresses are advantageous, later hot water is preferable. The eye should be frequently washed with water and Castile soap and boric acid, gram 0.7 to grams 30.0 of water (gr. x-℥ j) dropped in. When the discharge becomes mucous or mucopurulent, paint with solution of silver nitrate, gram 0.12-0.3 to grams 30.0 (gr. ij-v to ℥ j), and use stronger boric acid with sodium chloride added. In severe types wash eyes with bichloride of mercury, gram 0.045 to grams 500.0 (gr. ¾ to O j). Any thickening of the retrotarsal folds may be touched with alum or glycerite of tannin. Atropine is not necessary unless there is a corneal ulcer or other complications. Poultices should never be used. The eyes may be protected with smoked glasses.—*Diseases of the Eye.*

Calomel Injections.—In syphilis Fournier does not inject large quantities as was formerly the practice, but prefers a dose of gram 0.03-0.05 (gr. ½-5/6) injected every week or ten days from four to six times. He uses sublimed calomel, thoroughly porphyrized and washed with boiling alcohol. Of this gram 0.5 (gr. viij) is mixed with sterilized olive oil, grams 10.0 (℥ iiss), one c.c. (♏ xv) containing gram 0.05 (gr. 5/6) of calomel. If necessary one-fifth as much pure cocaine as calomel may be added. Fournier, having tried many forms of mercury and numerous vehicles, considers this the formula of choice. Calomel is more certain and more powerful than other mercurials, is less likely to cause stomatitis, gastro-intestinal symptoms and constitutional disturbance, and causes less local reaction. Moderate pain at the site of injection is not uncommon, but this is rarely severe.—*Revue de Thérapeutique.*

Black Draught.—In this, writes Lauder Brunton, there is one thing to cure by acting upon the intestinal secretion, another to help it by acting on peristalsis, another to make these act safely by lessening griping and flatus, and still another to make the compound more agreeable. The formula of the British Pharmacopœia is:

℞ Magnes. sulph.....120.0 (℥ iv)
Fl. ext. glycyrrhiz..... 30.0 (℥ j)
Tr. cardam. comp..... 45.0 (℥ iiss)
Tinct. sennæ..... 75.0 (℥ iiss)
Infus. sennæ.....450.0 (℥ xv)

M. et sig.: One to one and a half ounces.—*Action of Medicines.*

SATURDAY, DECEMBER 8, 1900.

AN IMPROVEMENT IN THE MANAGEMENT OF THE NEW YORK CITY HOSPITALS.

The first draft of the report of the revision of the Charter of the City of New York has a proposed Act on City Hospital Management of sufficient interest to the medical profession to excite considerable discussion.

The removal from the care of the Commissioners of Charities and Corrections of the management of Bellevue, the Fordham, the Gouverneur and the Harlem Hospitals and the placing of all control of these in a board of seven trustees, who shall serve without salary, is, we feel, a long stride toward certain ideals which never could be realized under the present state of administration.

To grasp the full benefit of such a proposed change and to be able to appreciate the scope for improvement that would be offered to these hospitals, one must combine a technical knowledge of the details of a hospital's management with a genuine desire for philanthropic work, and those who possess this knowledge read a special significance in the following clauses: "No member of the Board of Trustees shall receive any pecuniary compensation for his services, nor be interested, directly or indirectly, in the furnishing or performing of work, labor, services, materials or supplies of any kind, to, or for, said Hospitals by contract or otherwise," and, "No member of the aforesaid Board of Trustees shall hold any office of emolument under City, County, State or National government, except the office of notary public or commissioner of deeds or offices in the National Guard."

Our esteemed contemporary, *The New York Medical Journal,* in commenting on the proposed Act, professes much surprise at such a "radical," "incomprehensible," and "incongruous" change of policy in the management of this group of the city's hospitals, and hastens to assure its readers that if, by chance, they thought it was to be made in order to remove these hospitals from the sphere of "practical politics," the fact has not become generally known that they were suffering from any such cause.

There are more ways than one to account for facts not being generally known; but it is not the past management of these hospitals that is under discussion, but their possibilities under a liberal, untrammeled board of trustees of wisely selected unsalaried men, with perhaps one medical man among the seven.

Boston and Cincinnati are the only cities in the Union that have adopted this method of administration for their city hospitals, but the success of their experiment has justified the wisdom of the principles on which it was based.

In New York's problem the interest centers about Bellevue, for its efficient management means the best care that the city can give to the largest number of laboring men and women. The patients of Bellevue are not paupers but wage-earners, and the fact that they cannot pay for medical treatment should in no way make them feel that they are accepting an ignominious charity; and yet the working public do feel, whether justly or not, that to be taken to Bellevue Hospital is a stigma of pauperism. This is but popular prejudice and has nothing to do with the excellent medical treatment received at Bellevue, but is distinctly an outgrowth of the shifting political management of the hospital. To place it, therefore, under the same system of trustee management that is in force in private hospitals, and that has been so successful in the city hospitals of Boston and Cincinnati, will remove the feeling from the self-respecting. When Bellevue adds to its famed medical reputation the reputation of being one of the cleanest, best managed, and most honorably served hospitals in the city, it will become the people's pride as well as the physician's standby.

Those who are in argumentative mood inquire, with some logic, why only four hospitals should be selected for the change and why the other hospitals now controlled by the Department of Charities, should be omitted. The reason is one of expediency only and is the result of mature deliberation on the part of the Charter Revision Committee, who feared that failure might attend the change of system of the many city hospitals at once, but who were confident that the management of the four selected could be altered to the satisfaction of every one and that the change could ultimately be made for all.

With the change of management New York City, with the money, science and philanthropy that it has at command, can develop a type of modern municipal hospital that will equal any private hospital in the land.

The possibility of friction resulting from the half change is strongly urged by those who do not want any change at all. Practical difficulties certainly do exist, as the overflow of patients from the Bellevue group must be taken to the Island group and certain details of administration connected with the Charities Organization, such as the stabling of horses and the supply of drugs and power and heat which are connected with the Bellevue property. These details, however, are such that can be either harmoniously and justly attended to or can be used to rub up considerable friction, but the unsalaried board of trustees will not do much rubbing.

President Keller, the present Commissioner, has done all that any man could to improve the conditions of the hospitals in the Department of Public Charities; but the system and the inherited evils of administration have been too strong for him. His experience, however, will be of value to the new board of trustees of which he will be an ex-officio member, if the revision bill passes. It has been owing to his energy and effort that Bellevue has offered greater facilities than ever before to medical education by admitting to its bedside clinics the students of the University, Columbia, and Cornell Medical Schools.

It, therefore, strikes us as rather a bit of sentiment to quote President Keller as saying that he feared the proposed change might be designed to bring the hospitals more completely under the control of the leading institutions, and that, as they were intended primarily for the relief of the sick and only incidentally for educational purposes, the change was to be deplored. Any such generalized philanthropy must be made very sharp and clear. Hospitals are first, last and always for the sick, and Bellevue Hospital has always had the sickest of the sick in its wards, not only the worst cases but the greatest variety of them. This fact has attracted the best physicians and the best medical students to give their services as attendants and as internes to the institution, and in consequence it has had one of the best medical services to be had, and the hospital's fame and success have grown *in spite of the management*. The connection of the hospital with the University, Columbia, and Cornell Medical Schools has been its chief cause for congratulation. It is the energetic, eager interest of medical teachers that has given every patient the most thorough and careful handling and has kept the hospital from degenerating into a lazar house. It is, if the statement must be made openly, because, in addition to treating, so much more might be done than has been done for the comfort and consideration of the city's sick; so much more healing applied for the same amount of money expended; so much more freedom given to the doctors who are the mainstay and means of its existence to carry out the methods of treatment, that the revisers of the charter propose this radical change in the management of the specified hospitals.

SALT STARVATION IN THE TREATMENT OF EPILEPSY.

Common table salt was used by Hammond and Hamilton several years ago in the experimental treatment of epileptics with no apparent diminution of convulsions. It is a common experience that in the healthy classes, consumers of salt in large quantity are liable to be very irritable. This is especially marked in epileptics, as stated by Clark in a paper read at the Buffalo Academy of Medicine. He reports several epileptics at the Craig Colony, who, if unchecked, eat nearly two ounces of salt daily at meals in addition to the customary amount employed in preparing the dietary.

It will be remembered that Toulouse and Marchand last year ingeniously suggested that by reducing the salt in the epileptic diet the amount of bromides may be correspondingly materially decreased, the rationale being that bromine can substitute chlorine in the tissues. Animal experimentation proved that when dogs and cats

were fed on bromine and salt starved, the gastric juice contained bromhydric instead of chlorhydric acid. In the kidneys, brain and bone marrow, the proportion of bromine to chlorine found was two parts of the former to one of the latter. Bromine is not a foreign substance, but a true mineral constituent of the body. Thus it appears there is a good basis for the clinical fact that when an epileptic is under salt starvation, the bromides are more greedily absorbed in the tissues, and as it is the amount of bromides taken in the tissues, and the permanency with which such quantities can be induced to remain in the human economy, the value of Toulouse's method is obvious.

It is difficult to persuade epileptics to undergo voluntary deprivation of salt, and a semistarvation or a relapsing diet must be instituted. One of the best and easiest methods is the maintenance of epileptics on a milk diet. For a long time it has been known that a milk diet materially lessens the formation of toxalbumins in the intestinal tract, but, employed in conjunction with bromides, it has additional potency due to salt deprivation. Clark's dietary is a modification of that of Toulouse, and has the advantage over the latter in being much more palatable and easily cooked. It is as follows:

Breakfast: Milk, one pint.

Lunch: Two soft boiled eggs, farina, milk and sugar, coffee; or muffins made of eggs, farina, milk and sugar, and coffee.

Dinner: Bouillon unsalted or chicken-broth with a little rice; boiled beef unsalted or roast beef unsalted; potatoes.

Supper: Porridge made with farina, sugar, boiling milk; or milk and rice.

An occasional meal with the meat seasoned with a small definite amount of salt may be given, say sixty to eighty grams.

By this method the amount of bromide salt may be reduced by one half and the same therapeutic results may be obtained as before the method was instituted. Not one of the least of its virtues is the lessening by one half the chance of bromide poisoning. Toulouse cautions that in inaugurating the method the bromides should be decreased slowly. Patients should be watched closely in adjusting the balance between the decrease of sodium chloride and the substitution of the bromide salts. Toulouse prefers the sodium bromide, while Clark selects the tribromic mixture of ammonium, sodium and potassium. Nacke, Roux and Richet have all reported favorably in experiments of several months in long-standing cases of epilepsy. Its economy is obvious in epilepsy and other diseases where bromide sedation is needed over a long period of time. Sufficiently satisfactory results have now been reported for us to say that Toulouse's method is a real advance in our knowledge of the treatment of epilepsy by bromides, the chief sedative for this disease. It will be found especially of value where large dosage of bromides has not heretofore been possible because of the resultant toxicity, or in which high dosage has been inefficacious.

PURPURA RHEUMATICA SUCCEEDING ANGINA.

The relation between rheumatism and anginal affections has been the theme of many writers both here and abroad. Their articles have called forth increased attention to the sequelæ of the ordinary throat affections, and in the *Berliner klinische Wochenschrift*, November 5, 1900, A. Brück gives us the results of his own observations in the matter.

Attention once directed more intently to the cause of the rheumatic affections, it became evident that many of them followed closely upon some slight or perhaps severe tonsillitis. The investigations showed that it was well within the range of probability that the portal for the entrance of the infecting organisms was the adenoid tissue of the tonsils. From this origin, they find their way by means of the blood-stream to the various localities to renew their pernicious activity. The presence of streptococci, staphylococci and even of the pneumococcus of Fraenkel in the tonsils, the blood and the joints, has been clearly demonstrated.

Following this reasoning, acute articular rheumatism would be nothing else than a rather mild form of pyemic inflammation. The attending complications, *i. e.*, endocarditis, hyperpyrexia, hemorrhagic skin affections, all go to prove the conclusion.

The reason that in every case of rheumatism we have not yet succeeded in finding an antecedent anginal affection may be ascribed to the similar condition of a lymphadenitis in which we fail to find the initial surface wound through which the germs found entrance. The little wound or abrasion may be long healed over and forgotten before the more serious metastasis is discovered. The reason for the attack by the

germs on the articulation rather than on other anatomical parts is perhaps found in the fact that they are the parts of least resistance, as they are also in the other acute infectious diseases such as diphtheria, tuberculosis, and gonorrhea. The skin affections coincident with rheumatic attacks, erythema nodosum, erythema exudatum multiforme, peliosis rheumatica, may likewise be said to be dependent upon micro-organisms for their production.

Brück says that their occurrence succeeding angina is not nearly so infrequent as has been stated by others. Who would think of examining the skin of the entire body in every case of sore throat in daily private practice? On the other hand, who would question a patient suffering from such skin affection as to whether he had had a previous sore throat? Even if the query were put, the angina may have been so mild that it escaped the patient's memory.

Brück chooses four cases from his practice which illustrate his theory. In every case there was either a well-marked petechial affection of the skin or some rheumatic trouble, or both, succeeding a tonsillitis lacunaris. The condition succumbed to the salicylates. In one patient the entire body, excepting face, neck and chest, was covered with petechiæ. In others, only the legs were covered with a mild petechial eruption. In all of the patients the beginning of the rheumatic symptoms followed so closely after the cessation of the throat symptoms that the causal relationship seemed to admit of no question whatever.

These latter were so unimportant in three cases as to awaken no anxiety whatever in the mind of the patient. The rheumatic conditions were muscular as well as articular in character, from which we glean the identical origin of the two. Cases which have been cited by Babes and Reher agree fully with the idea advanced by Brück.

The etiological dependence of angina lacunaris, acute muscular and articular rheumatism and the purpuric skin eruptions is thus satisfactorily dismissed by him as being absolutely proved. It might not be amiss to declare that in this category would belong otitis media. Black has shown this connection in publishing his cases. Gradenigo has done likewise. It would certainly be of value if more time was given to searching for such causes as above enumerated in all cases of rheumatic affections and their accompanying skin eruptions

ECHOES AND NEWS.

NEW YORK.

Smallpox Situation.—Since last week's report in the Medical News 34 additional cases have been reported, thus making to date a total of nearly 40 cases.

Roentgen Society of United States.—The first regular meeting of this Society will take place in New York City, Grand Central Palace, December 13 and 14, 1900.

Bequests to Hospitals.—By the will of the late Mr. Robert G. Dun the following institutions are to receive $5000 each: The Presbyterian Hospital, St. Luke's Hospital, Mt. Sinai Hospital, and the New York Institution for the Instruction of Deaf and Dumb.

New Immigrant Station.—The Bureau of Immigration will be transferred from the present quarters to the new station on Ellis Island the 15th of this month. The transition from the cramped and badly arranged quarters which the bureau has occupied since the fire that destroyed the old station on the island in 1897 will be marked. One has only to remember the old ramshackle structure to be able to appreciate the magnificent and admirably arranged new quarters. Situated on one of the most prominent locations in the harbor, the new station is an imposing as well as a pleasing addition to the picturesque water-front of the metropolis.

Obituary.—Dr. R. B. Lincoln died last week of a peculiar type of intestinal obstruction, at first diagnosed as appendicitis. He was born April 17, 1841, in Benchertown, Mass. At the close of the war he took a three-years' course in medicine in Harvard, graduating in 1868. He served for a year as house surgeon in the Massachusetts General Hospital in Boston, after which he took up practice in this city. He was a member of the Loyal Legion, the New England Society, University, Amherst Alumni, Harvard Medical, and the Mendelssohn Glee Club, the American Medical Association, the New York Academy of Medicine, and the American Academy of Medicine.

Scarlet Fever on Long Island.—Scarlet fever is epidemic to such an extent in the village of Baldwins, L. I., that Thanksgiving festivities planned, including an entertainment in which many children were to take part at the Methodist Church, had to be postponed because of the malady.

Tuberculosis Hospital Plans.—The report of the Board of Trustees of the State Hospital for the Treatment of Incipient Pulmonary Tuberculosis was received November 30th, by Robert W. Hebbard, Secretary of the State Board of Charities. The report says:

"The Board of Trustees was appointed in May of this year, and from that time until the end of

September the members were engaged in inspecting the various sites in the Adirondacks which were offered to us or which we thought might be eligible. Twenty-six were examined and discussed. It became clearly apparent to us almost at once that it would be impossible to place the institution more than a mile from a railroad, as the amount of truckage necessary in the construction and maintenance of the hospital would be so great as greatly to injure the usefulness of the institution. This narrowed our choice very much. With the aid of the State Architect, a plan of requirements for the institution was made, which were fifteen in number, beginning, of course, with sufficient water supply. Next came the quality of the soil, the elevation, the sufficiency of the protection from the wind either by forest or hills, accessibility of the site from the nearest railway, etc. Several sites were visited three or four times. By the end of August the selection had narrowed itself to three or four sites, and at the end of September, at a meeting held in Albany, the trustees selected a site at the west end of Lake Clear, Franklin County.

"By the terms of Section 7 of the Act incorporating the institution such site is subject to the approval of the State Board of Health and the Forest Preserve Board. The Secretary of the Board of Trustees of the State Hospital notified these two boards of the approval of our selection of the site. The Forest Preserve Board visited the site, as did also Dr. Daniel Lewis, the President of the Board of Health. A public hearing was had on October 11th by these boards of approval, but no decision has been rendered. This is all the report that we can make as to the affairs and conditions of the hospital. The appropriation this year granted to us by the Legislature under the act of incorporation was $50,000. The only expenses of the institution so far have been the traveling and other expenses of the trustees.

"We hope that the site may be purchased at from $10,000 to $12,000. More or less of the appropriation will be expended this autumn in maintaining roads, clearing the ground, preparing reconnaissance surveys, and making preliminary excavations, but certainly some part of our appropriation will remain unused. As to the amount required by us for operating expenses next year, it may be said that there is so little probability of the hospital being ready for the reception of patients before next autumn at the earliest, that we need only ask for a small amount, and this amount is rather in the nature of a precaution. But we think the sum of $21,600 should be set aside as a precaution for the maintenance of a hospital during the months of October, November, and December, in case it shall be ready for patients at that time.

"In regard to the amount to be appropriated for the construction of the hospital by the next Legislature, we are of the opinion that a hospital cannot be built and equipped under $200,000, and we may add that our opinion is formed from information given to us lately by the State Architect. The preliminary plans are now being prepared by him. It is our purpose to submit copies of these plans to a number of prominent men of America and Europe for their criticism and suggestions, so that when they are laid before you they will present the result of the best medical judgment that we can obtain."

Dr. Noyes and the New York Eye and Ear Infirmary.—Dr. Henry D. Noyes was a graduate of the College of Physicians and Surgeons in the year 1855. After serving on the house staff of the New York Hospital, he went to Europe to continue his studies. Devoting himself to special work in the ophthalmic clinics there and latterly a student of Von Graefe in Berlin, he returned to America and in September, 1859, was appointed assistant surgeon to this Infirmary. In November, 1864, he was made surgeon. From 1873 until 1898 he served as executive surgeon and on October 23, 1900, his resignation as a member of the surgical staff was received by the Board of Directors—by the Board at whose councils he had sat for a period of thirty-six years. This long service of one, who during nearly the entire time held foremost position in conducting the affairs of the Institution, covers more than half the period that has elapsed since the foundation of the Infirmary. These years have seen marked changes in the growth of the Institution and a brief reference to the statistics, furnished by our Annual Reports, may not be out of place. In the year 1859 there were 4176 new dispensary patients and 144 in the wards. In 1899 there were 47,684 new dispensary and 2257 house patients. In 1859 the surgical staff consisted of 9 men. Now 83 medical men are engaged in the work. In 1859 it was an Eye Infirmary. Now there are the three departments of the Eye, Ear and Throat. The well-ordered Hospital of to-day, with its superintendent and clerks, its isolated cataract wards and pavilion for contagious ophthalmia, its training school for nurses, school for instruction for graduates of medicine, its annual volume of scientific transactions, its valuable medical library, owes in no small way its preeminence to the wise forethought and ceaseless activity of Dr. Noyes.

The Rules and Regulations of the Infirmary were largely the result of his careful study, and it was perhaps characteristic of his unselfish devotion to the Institution that, shortly before his resignation of the position of executive surgeon, he prepared rules that gave this office largely increased powers and left the enjoyment of them to his successor.

Bringing as he did to the discharge of his professional duties a vast knowledge of medicine, a facility and originality in operative procedure, he was unsparing of self in his devotion to those who came under his care. He was

prompt in recognizing the value of suggestions made by others in his field of work, and his distinguished position as an author and teacher added to the fame of the Institution both at home and abroad. Throughout the years of his connection with the Infirmary Dr. Noyes contended for an increase in our scientific and laboratory work. He urged that there could be no effective and perfectly developed charity that is not associated with scientific investigation.

Dr. Noyes died on the 12th of November, 1900. It is fitting that the medical staff of this Institution, to the service of which he had devoted all the years of his active professional life, should record their appreciation of the work of a man who has contributed so largely to make the Infirmary what it is. It is proper that at this time, feeling the irreparable loss they have sustained in his death, they should, in the spirit in which he lived, dedicate themselves anew to a service, not alone as ministers to humanity, but also as ministers to knowledge in medicine.

The Alcohol Question.—A meeting of the New York State Medical Alliance will be held at the New York Academy of Medicine, 17 West 43d Street, Thursday, December 13th, at 8 P. M. Dr. Winfield S. Hall, A.M., M.D., Ph.D., (Leipzig), Professor of Physiology in the Northwestern University Medical School, Chicago, will read a paper on "Ethyl Alcohol: Its Biology and Its Relation to Physiology, to Pharmacology, and to Therapeutics." Discussion of the paper is expected by Professor Conn of Wesleyan University; Professor C. A. Herter of the University and Bellevue Medical School; Professor Woodbury of the Philadelphia Polyclinic and College for Graduates, formerly Professor of Materia Medica and Therapeutics in the Medico-Chirurgical College of Philadelphia, and by others. Dr. Andrew H. Smith, President of the Alliance, will preside. The medical profession is cordially invited.

PHILADELPHIA.

Resignation of Dr. Lloyd.—Dr. J. Hendrie Lloyd has resigned his position as neurologist to the Philadelphia Hospital.

German Hospital Donation Day.—On Thanksgiving Day the German Hospital received over $8000 in cash. In addition to this the firm of C. F. Rumpp & Sons contributed $5000 to endow a free bed for the benefit of their employes.

Physician for Department Store.—Gimbel Brothers have recently installed a woman physician in their department store. Female employes are treated at her office in the store, a purely nominal charge being made for the services rendered.

"Ostrich Man" Visits the City.—Harry Harrison, of Syracuse, N. Y., gave his annual exhibition of swallowing pieces of glass, nails, tacks, broken knifeblades, etc., at the Medico-Chirurgical Hospital last week. He seems none the worse from the operation which he underwent in Baltimore last year.

Disinfecting Barges Sent to Cuban Ports.—Two disinfecting barges, which were converted from schooners by the Kensington Engine Co., have been sent for service at Matanzas and Cienfuegos, Cuba. Neither is self-propelling. They contain full apparatus for the handling of formaldehyde, sulphur dioxide, etc. Another barge for quarantine work in Porto Rico is now under course of construction here.

New Trick of Sneak Thief.—A prominent physician of the city recently had a well-dressed caller who waived his priority of examination in favor of a second caller who was in a hurry. The latter left his hat, gloves, silk umbrella, and eye-glasses in the outer waiting-room. When he came from the consulting-room these articles, as well as the polite stranger, were missing. A description of the man has been given to the police in the hope of preventing a repetition of the act.

Osteopaths Desire Special Laws.—A bill to regulate the practice of osteopathy in Pennsylvania will be introduced by osteopathists at the next session of the Legislature. At a meeting of their State Society in Harrisburg last week it was stated that they would not antagonize any system of treating disease. The plea that osteopaths should come under the jurisdiction of the present State Medical Boards they consider to be a plea for protection of medical trusts. Efforts are, therefore, to be made to secure the appointment of a board of osteopathic examiners who are specialists in anatomy and who are conversant with the osteopathic system of treatment.

Report of State Factory Inspector.—State Factory Inspector Campbell has issued his report for the year ending October 31st. In the main the results of the year's work are satisfactory. The bake-shop law has greatly improved the sanitary condition of the shops, many of the poorer ones having been abandoned, but as a result home workers are rapidly increasing. This increase of home workers has a tendency to reduce wages and spread disease. Through the aid of the Boards of Health in Philadelphia and Pittsburg a large amount of clothing made in homes where contagious diseases existed has been located and destroyed. The cooperation of these two departments is of the greatest importance. Inspector Campbell recommends the appointment of ten additional inspectors and the establishment of suboffices of the department in Philadelphia and Pittsburg.

Pay for School Physicians Urged.—The Committee of Medical Inspection of the Public Education Association has adopted a resolution recommending that the medical inspectors of schools

be paid a salary of $500 each for their services during the school year, from September to May, inclusive. This, it is believed, would insure uniform work and a definite and responsible organization. The Committee suggests that the corps of visiting physicians consists of 200. The inspectors held a meeting Saturday to consider a constitution for their proposed association. It was only partially adopted.

Extensive Operation on Neck.—Dr. W. J. Hearn reported an instructive case at the Academy of Surgery Monday evening. The patient was a physician, the operation being one for secondary lymphosarcoma of the neck. A portion of the internal jugular vein was excised, the pneumogastric, phrenic, and sympathetic nerves were divided, and a portion of the thoracic duct removed. No immediate ill effects followed the division of these important structures, and speech was preserved. A fistula through which the chyle escaped was present for some time, but this finally healed. The patient died some time afterward from a return of the growth and chronic sepsis.

Operative Treatment for Cirrhosis of the Liver—Dr. Chas. H. Frazier reports a case operated upon nearly five months ago at the University Hospital which shows very satisfactory results. Diuretics and tappings had produced no effects. The abdomen was opened, the peritoneum at each side of the wound rubbed with gauze to produce irritation and the omentum sutured to the parietal layer. The wound was closed without drainage. The patient was tapped on the thirteenth day after the operation and a second time on the thirty-sixth day, since which time no accumulation of fluid has taken place. No other treatment was instituted except necessary laxatives. There seems to be no doubt of the success of the operation in this case. Dr. Frazier believes that suprapubic drainage after such operation is an unnecessary risk of infection and advises against its use. The abdomen should be closed and tapping resorted to while venous channels are forming in the adhesions. The operation should be done under local anesthesia if possible, as such subjects bear ether narcosis very badly.

County Medical Society; Treatment of Gonorrhea; Cystoscopy in Women.—At the meeting of November 28th Dr. Edward Martin detailed the treatment for gonorrhea which he has adopted after a thorough trial of various methods. The most important part is local treatment. Hand injections of protargol or other silver preparation are begun at once when the case is seen. A few drops are let fall between the separated lips of the meatus to reach the parts which the nozzle of the syringe passes by. The anterior urethra is then filled and the solution retained for three minutes. This is done every two hours, the silver solution being gradually weakened after a day or two. Irrigations of potassium permanganate, 1-6000, are used night and morning. This is gradually strengthened up to 1-3000 and after six or eight days used only at night. Autoirrigation is taught in most cases. Internal treatment consists in making the urine bland. Lithia tablets are given six times a day with a glass of water each time. Salol is given in five-grain doses four times a day. The diet is largely determined by what agrees with the patient, pastry and such articles being of course forbidden. Moderate exercise is allowed and a prolonged hot bath given every night. Under this treatment 25 per cent. of the cases are cured in from six to eight days. Others take twelve to fifteen days and a certain percentage takes longer, as they do under any treatment which may be instituted. Chordee, painful urination, etc., almost never occur. If gonococci are found after fourteen to sixteen days, treatment is again instituted with the addition of an astringent injection. The silver injection should be used, as long as gonococci persist. When the discharge lasts for six to eight weeks the urethra should be explored for the cause, milking the follicles from behind forward by means of a dilating instrument, posterior irrigations, and massage of the prostate may be indicated.

Dr. John G. Clark discussed the subject of cystoscopy in women. He advises the use of the Nitze cystoscope first in cases demanding exploration of the bladder. It is the best instrument for office work and for preliminary examination under any circumstances. Its use is less annoying to the patient and for this reason her cooperation in subsequent procedures is more likely to be secured. This instrument is valuable in locating points of disease and affections of the bladder generally occupy only a small area. This is true even of cystitis in which the trigonum is usually the only part involved. By systematic rotation of the instrument the whole interior of the bladder may be gone over. When the portion of the bladder at fault is determined the Kelly apparatus is used for any further work that may be necessary. Dr. Clark has noticed that operators, especially those abroad, who have trouble with the Kelly apparatus do not place the patient in the proper position. The shoulders and chest are not kept flat upon the table and in some instances the abdomen was supported instead of being kept free to allow ballooning of the bladder.

CHICAGO.

Warden of Cook County Hospital.—There is considerable opposition being manifested against the reelection of James H. Graham as Warden of this Hospital. The medical profession is almost a unit in favor of placing a physician in the position of Warden rather than to reelect a layman.

Resignation of Dr. Stehman.—Dr. Henry B. Stehman has resigned the position of medical

superintendent of the Presbyterian Hospital, after serving for fifteen years in that capacity. A successor will be chosen before January 1, 1901.

Transfer of College of Physicians and Surgeons.—The terms of the contract under which the College of Physicians and Surgeons, which is now affiliated with the University of Illinois, will become ultimately the property of the University have been made public. The arrangement is one by which in the course of a number of years, estimated at from twenty to thirty, the University will be able to pay for the College out of a fund accumulated from a certain portion of the profits to be set aside each year. According to Dr. Quine, the University of Illinois assumes no financial responsibility in the transaction. The College is the property of a stock company, which owns a large site of land and several buildings on the west side. For the rent of these the University agrees to pay $12,000 a year out of the gross receipts to the directors of the College. Then, after paying the expenses of operation, two-thirds of what is left will be used to pay professors' salaries, and the balance of the receipts will be invested by the University in the purchase price fund. When this fund reaches $217,000 it is to be paid over to the directors of the school, and title will pass.

Resignation of Dr. Christopher.—Dr. W. S. Christopher resigned from the Board of Education, after having served since 1898. He introduced a system of child-study and a system of medical inspection in the schools. The ergograph, measuring the mental qualities of pupils, was also adopted at his suggestion.

Donation by Dr. Fenger.—Dr. Christian Fenger recently donated to the library of Rush Medical College a collection of books which represents the German surgical literature of the last fifty years. There are about five hundred volumes in all.

Seek to Close Opium Dens.—Failure of the Chicago police to do their duty and close all opium dens in the city has led to the filing of sixty-eight cases, alleging violation of the pharmacy law, by the State Board of Pharmacy. Six cases were dismissed in Justice Hall's court because the board's attorney believed it impossible to secure a conviction with the Clark Street juries summoned by the constables.

Physicians' Club.—At a meeting, held November 25th, the subject of the physician as a writer of medical literature was discussed. Dr. G. Frank Lydston spoke on the topic "Should the Physician Write?" He answered the question in the affirmative, saying that persistent writing enables the physician to acquire a knowledge of medicine and surgery which could not be obtained in any other manner. As models of literary style he mentioned the writings of Van Buren and Fothergill. Dr. George H. Simmons pointed out the common faults of the writings of medical authors. Most physicians write too long papers. They should be short, so that editors would be able to present their readers with greater variety of topics. Long articles are only read by about one per cent. of the readers. Many papers bristle with unnecessary details. Meaningless titles were dwelt upon and examples given, as, for instance, "interesting report of surgical cases," "a few surgical problems," etc. He urged the use of central and side headlines to guide the reader. Probably three-fourths of all papers prepared for reading before medical societies are written to satisfy the Secretary. They are, therefore, prepared hurriedly and the subjects are not well thought out. Faults in case-reporting were dwelt upon and illustrations given. Dr. Henry F. Lewis spoke of the medical writer from the standpoint of the reader. The busy practitioner can only read a few medical journals and these should be the best. The medical writer speaks too frequently with an authority that is not his own. There is too much compilation and not enough of the experience and observations of authors embodied in articles. Too much space is devoted to what this and that man have said regarding a certain subject. This is unnecessary, as those interested can look up the literature themselves. Articles are not sufficiently concise. Greater condensation is necessary. The average writer consumes too much time and space with prefatory observations, or long, verbose introductories. Brevity, without vagueness, is desired. Subjects should be well divided; there should be a liberal use of central and side headlines, so that the reader can skip paragraphs here and there, if necessary. Dr. George F. Butler spoke on how to write well. A prerequisite to writing well is to think well. He cited a few instances of eminent authors with the definite purpose of showing that association with great minds, through a diligent perusal of their work, will be found the surest means of acquiring the art of logical, refined, and cultivated expression. Newspaper editorials are fully equal in style to the best magazine literature, particularly those written for the great dailies, in that they were examples of concise, logical, reasoning, combined with discriminating observation of the leading events of the day.

New State Sanitarium.—A State sanitarium for consumptives will be one of the recommendations made by the State Board of Health in its forthcoming biennial report. The Board also will join with the State Board of Charities in favoring a provision for the especial care of epileptics. The Health Board will ask that the powers of township boards be extended so that they will have the power to punish persons violating rules tending to check the spread of contagious diseases. It will also recommend legislation providing for boards of health in counties not under township organization, where the State

Board now exercises local jurisdiction. An examination for funeral directors, embalmers, and undertakers will be held by the State Board in Chicago on December 19th. An examination for physicians, midwives, and other practitioners will be held in Chicago on January 9, 10 and 11, 1901.

Cook County Hospital.—The *Chicago Tribune* comments as follows on the county hospital situation: "Perhaps sufficient evidence has not been submitted to the public to convince everybody that the administration of the County Hospital has been inefficient and unworthy during recent years. There is, however, a general impression, which is only too well justified, that the hospital has been run as a political rather than as a charitable institution and that the public service will be promoted by a refusal to reappoint the present warden. This being the case, the new President of the County Board, who has the appointing of the warden and the heads of other important county institutions, should perform the duty of making these appointments with care and circumspection. He should not appoint men who are pressed on him by politicians, through whom they hope to get control of the county institutions. He should select men of character, experience, and independence, who will administer the affairs of the hospital, for instance, in such a manner that the patients may be well cared for, while the funds of the county are not squandered. The man who will fill the hospital, the insane asylum, or the poorhouse with political bummers and favorites, who assists in putting through contracts of a dubious nature, or who accepts supplies when they are not what the contracts call for as to quantity or quality, is not the kind of man the taxpayers want or the President of the County Board should appoint. There should be at the head of such an institution as the County Hospital a man possessing absolute integrity and also sufficient intelligence to insure honesty in subordinates. He should make it his special duty to see that the patients get their rights, that the medical and nursing staffs are efficient in all respects, and that the business affairs of the hospital are managed as economically and carefully as are those of a commercial establishment, thus safeguarding the interests of the taxpayers. If the President of the County Board will take his time he can discover such a man—a man who will be the catspaw of no politician, and in whom the citizens of Cook County will have perfect confidence."

GENERAL.

St. Louis Medical Society.—At the last meeting, held December 1st, Dr. Hugo Summa read a paper on "The Floating Tenth Rib and Its Diagnostic Value."

Western Surgical and Gynecological Association.—The next annual meeting of this Association will be held at Minneapolis, Minn., December 27 and 28, 1900. An invitation is extended to surgeons and gynecologists of the Great West to attend this meeting and take part in its deliberations. As the meeting is to be held during the Christmas holidays those engaged in teaching in the medical schools will be able to attend without interfering with their college duties. The preliminary program suggests an interesting and full meeting.

Training School for Nurses, Freedmen's Hospital.—The United States Civil Service Commission invites attention to newspaper announcement issued November 23d for an examination for the position of Superintendent and Head Nurse, to be held December 19-20, 1900, and calls attention to the fact that the Department desires that preference in certification be given to unmarried women between twenty-five and fifty years of age, instead of between twenty and twenty-five years of age.

Cheyenne's Water Tainted.—Cheyenne, Wyoming, has had an epidemic of typhoid fever for several weeks, and the citizens have been at work to locate the cause. A report shows that the water supply of the city is contaminated with typhoid bacteria. In one instance no less than four masses of refuse were located near the filter-bed, and one of them directly over it.

Honor to Dr. Halsted.—Dr. W. S. Halsted, Yale, '74, of Johns Hopkins University, and formerly of New York City, has been elected as honorary fellow of the Royal College of Surgeons, London.

Smallpox in a Michigan City.—According to Secretary Baker of the State Board of Health, who was called to Winona to investigate the epidemic in that city, the disease is evidently smallpox of a mild character and the mortality about 2 per cent. It is said that there are over three hundred cases, mostly in the Fourth Ward, which is largely a Polish settlement.

Faith Curists Held for Murder.—Elder Eugene Brooks of the branch of the Dowie Zionites of Victoria, B. C., and W. W. Maltby, a disciple, were arrested last week in that city at the close of an inquest held regarding the death of Maltby's three-year-old child from diphtheria. The two are charged with murder.

Yale Medical School.—The plans for extension of the Medical School and its transfer to Cedar Street opposite the New Haven Hospital, where all the needed front has just been acquired, are now being actively pushed. If present hopes are realized, a few years more will find the school in its new quarters and rapidly regaining the importance which it had in the early part of the century. The first step will be the removal of the dispensary to Cedar Street.

Entrance to Medical School Raised.—At the monthly meeting of the Board of Regents of the University of Michigan it was decided to

raise the requirement for entrance to the medical department; that practically a two-year course in the literary department will be required for admission. Heretofore the same grade of entrance examinations has prevailed for both departments, and, as a consequence, a number of inadequately prepared students have slipped in who later have made a failure of their work in the school of medicine.

Cancer in London.—London medical science is being directed toward the elucidation of the problem of the causation of cancer. A cancer research laboratory has just been opened at the Middlesex Hospital, to be entirely devoted to the systematic investigation of cancer. The Middlesex Hospital is alone among the great London hospitals in admitting inoperable cases of disease, where the only hope is that death may come without much more pain. Some sixty of these hopeless cases will be now under close scientific scrutiny.

Michigan Smallpox Grave.—The smallpox situation in the upper peninsula is quite serious, in view of the fact that lumbermen ill with the disease come into the city hospitals laboring under the impression that they have some trifling ailment. Most of the outbreaks have resulted from such cases, many persons being exposed on railroad trains and in other public places.

Woman's Medical Club.—A Woman's Medical Club has recently been formed in suburban New Jersey, which limits its membership to women who are regular physicians, the qualifying adjective being strictly adhered to. The object of the club is mutual helpfulness, and the discussion of medical questions, as well as the promotion of sociability among women physicians throughout the State. Fifteen members were enrolled at the first meeting, including representatives from the Oranges and Newark, Jersey City, Montclair and Roselle. The officers are: President, Dr. Katherine Porter, Orange; Recording Secretary, Dr. Mary D. Hussey; Corresponding Secretary, Dr. Isabel M. Geddes of Newark; Treasurer, Dr. Augusta M. Madison.

Pan-American Medical Congress.—The "Morro Castle" will leave New York December 22d and will be back in ten days, three days down, four days in Havana, and two days back; price of the trip $60. The hotels in Havana are as follows: Telegrafo, Mascotte, Ingleterra, Pasje, and Roma; rates from three to five dollars a day, everything included. Trip from New York and return, including passage, hotel, meals and all, $80. As regards the reports that yellow fever is prevalent in Havana, the following communication to the *New York Times* from Dr. Juan Santos Fernandez, President of the Congress, may be of interest: "It is very necessary for the success of the third Pan-American Medical Congress, which is to be in session in Havana, Cuba, the 26th, 27th, 28th, and 29th of December, 1900, that the physicians of the United States should be informed that yellow fever disappears or is very rare in this city at that season, and that already the number of cases have greatly diminished, therefore there is no occasion for fear on their part in coming to Cuba in the latter part of December."

Arsenic Poisoning in Manchester.—The situation at Manchester seems more grave than last week's report in the MEDICAL NEWS would indicate. The victims of arsenic poison in beer now number more than sixty dead and more than one thousand ill. The area affected is confined within a hundred-mile radius from Manchester, but the panic among beer-drinkers has spread almost throughout the whole country. It has been completely established that the cause of the poisoning is arsenic in the sulphuric acid used in the manufacture of glucose or sugar which the English brewers employ in place of malt and hops in making cheap beer. The poison has thus far been traced to only one establishment which supplied sugar for several breweries in the Midlands and the north. The commercial sulphuric acid in this country is made from pyrites, almost all of which come from Spain. There is always a trace of arsenic in it. The offending firm argues that there must have been an undue proportion of the poison in the lode from which their supply came. At all events, an analysis shows that some beers sold in saloons this week contain arsenic sufficient to kill any persistent drinker. As a result of the warning of the authorities hundreds of thousands of gallons of beer have been poured into the sewers of Liverpool and Manchester by brewers and retailers. The scare has caused a strong revival of the agitation in favor of the compulsory use of malt and hops instead of cheaper substitutes. A Government inquiry will probably be ordered and it is likely that the subject will secure the attention of Parliament.

In the Learned Professions.— The Bureau of Statistics of Labor of Massachusetts issued December 1st an analysis regarding the learned professions in Massachusetts, the like of which has never been published before. The figures are those of the last State census of 1895, but they are doubtless about equally applicable to to-day. The classification under the head of religion includes such persons in the service of religion as sextons, superintendents of cemeteries, secretaries of religious societies, and others not strictly clerical. The legal profession is stretched to include not only lawyers, but clerks and officers of courts, justices, conveyancers, notaries, and solicitors. Under the head of medicine are included physicians and surgeons of the different schools, chiropodists, clairvoyant medical practitioners, dentists, manicures, and midwives. Including these, there are in the service of religion 4597 persons in the State, 2781 engaged in the legal profession, and 5800 in the practice of medicine. Dividing the total population by these figures, it appears that there is one religious

worker for every 544 persons in the State, one legal light for every 899 persons, and one medical practitioner for every 431.

There is a great difference between different localities regarding the proportion of these persons. Suffolk County, which includes Boston, Chelsea, Revere, and Winthrop, but consists largely of Boston, has 1245 in the service of religion, 909 in the service of law, and 1886 in the service of medicine. This is all out of proportion to the remainder of the State, showing how professional people crowd to the large centers. In Suffolk there is an average of one person in religious service for every 434 persons, one in law to every 594 persons, and one in medicine for every 286 persons. This shows that there must be a remarkable excess of doctors in Boston, for the proportion nearest to this is 377 in Nantucket County, and next is 431 in Hampden. In Boston alone there is one religious service to every 415 of population, one to 576 in law, and one to 278 in medicine.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, November 28, 1900.

THE STRUGGLE BETWEEN THE STAFF AND BOARD AT THE NATIONAL HOSPITAL FOR THE PARALYZED AND EPILEPTIC—THE HOSPITALS COMMISSION—CLOSE OF THE INQUIRY—EVIDENCE OF MRS. RICHARD CHAMBERLAIN—SIR MICHAEL FOSTER ON MEDICAL EDUCATION—DEFECTS OF THE GREAT LONDON HOSPITALS—WANT OF LABORATORY FACILITIES FOR THE INVESTIGATION OF DISEASE—HEALTH OF KIMBERLEY DURING THE SIEGE—TOBACCO IN WARFARE.

The controversy between the staff and the board or rather the secretary-director (for the board appears to be a one-man power) of the National Hospital for the Paralyzed and Epileptic still continues to be waged hotly in the columns of the *Times*. The board has passed a resolution that "In view of the publications in the press injurious to the interests of the hospital an inquiry should be held into the charges formulated by the staff against the domestic condition and management of the hospital and that some independent legal authority be requested to conduct such inquiry." The staff point out that possibly it is the board's intention to limit the inquiry to domestic matters, while their demand was for an inquiry into the constitution and management of the hospital. If the board intends to so limit the inquiry the staff will decline to be party to it. The domestic condition of the hospital is only a part of their charges. They further point out that the board being one party in the dispute are scarcely in the position to nominate their own tribunal, that the constitution of the hospital is so faulty that the staff while giving gratuitous services is disfranchised, that a paid official whose position in similar institutions is a subordinate one has gradually been allowed to assume an anomalous position, and that by his interposition as middleman between the board and staff harmonious and useful cooperation between these two bodies has become impossible. The staff, therefore, seeks direct representation on the board as the only means of arriving at a better understanding with them. In spite of the lengthy correspondence on the subject no proper reasons have ever been given why the demand for two seats by the staff on a board of twelve has been refused. The following are the reasons assigned: "The staff being officers and servants of the hospital should not be included in the governing body. They are charged with duties and questions relating to their discharge may arise. The independence of the board would disappear in the company of members of the staff. The claims of mere suffering would be overlooked and preference given to 'cases'. Though the members of the staff would only number two they would always speak with the whole force of their own medical committee and by threatening hostilities could always enforce their views." In a medical journal there is no need to reply to these silly arguments. The most weighty document which has appeared on this question is a letter in the *Times* signed by Lord Lister and the senior surgeons and physicians of all the hospitals in London having more than 100 beds, and by other medical leaders. It urges the governors to put an end to the controversy by granting the representation asked for which can only strengthen the board of management in wisely carrying out the great charitable work entrusted to it.

The Hospitals Commission which has returned from South Africa has held its last sitting in London. The only witness examined was Mrs. Richard Chamberlain, sister-in-law of the Colonial Secretary. She said that she had visited several hospitals, but considered herself an authority on only one, No. 1 Hospital at Wynberg, Cape Town. She was politely told on three occasions that no visitors were allowed. She ultimately got an order to visit from General Walker. Permission was given for three days a week, but she went every day. The whole place was in a horrible muddle. There was no organization and though money and stores were unlimited the place did not look like it. Proper convoys were not provided to bring patients from the station to the hospital. The typhoid were not separated from the surgical cases. Everything was short—splints and every necessary utensil from cups and saucers to bedpans. There were not sufficient air-cushions, air-beds, or hot-water bottles. Nurses were deficient although Cape Town was full of them. The patients were

dirty because there was not sufficient warm water to keep them clean. The military huts were swarming with vermin. The orderlies take the sheets of typhoid patients, wash them in cold water, dry them, and use them again without disinfection.

Sir Michael Foster, M.P., Professor of Physiology in the University of Cambridge, distributed the prizes to the students of St. George's Hospital Medical School and delivered an address on Medical Education. He said that he was oppressed by the thought that the opportunities offered by the great hospitals for the advance of medical knowledge were not adequately laid hold of. Complaints were made by the public that hospitals were used for "experiments." But this was mere kicking against the pricks. Whenever a patient placed himself in the hands of a physician his case became the subject of investigation. Every touch of the surgeon and every counsel of the physician was necessarily an experiment, for the result was never absolutely certain and the practitioner was always prepared to profit by the teaching of that result. These two characters were the essence of a scientific experiment. He complained that in our great hospitals the teachings of those multitudinous experiments were not laid hold of as completely and as fully as they might be. The analysis of the phenomena at the bedside and in the post-mortem room was not carried out as exactly, as completely, as fully and as systematically as it might be. In none of our great hospitals was the chemical, physical and bacteriological analysis of cases as complete as it should be. In the great metropolis of London the hospitals were not so well equipped for these purposes as in America and on the Continent or even in the English provinces.

The annual report of the Medical Officer of Health of Kimberley for 1899 is an interesting document. The report says that the chief feature which influenced the health of the town during the year was the state of war of the last two and a half months. The siege continued until the middle of February of the present year. For the part of the division of Kimberley which was in the enemy's hands the medical officer is unable to give statistics. But he states that among the enemy encamped at Magersfontein and at the various stations and trenches round Kimberley there is abundant evidence that enteric fever was very prevalent. During the few weeks preceding the siege there was an abundant influx of refugees from Johannesburg and elsewhere causing crowding in the dwellings. The exigencies of war and the restrictions under which the besieged were placed caused a marked increase in the death-rate. During the first nine months of the year the health of the town was good and compares favorably with other years and with other towns in the colony. The population was 163,000 whites and 23,200 colored. The death-rate for the first nine months was only 17 per 1000. But for the entire year it was 42.6, which shows the tremendous effect of the siege. It was amongst the young children who are most easily influenced by adverse circumstances and who therefore furnish a delicate index of public health that the death-rate was phenomenally high. For the year ending June 30, 1890, 348 colored infants per 1000 registered births and 304 Europeans died.

The war, says the *Lancet,* has taught many things. Perhaps nothing has been more demonstrated than the important part played by tobacco in the soldier's existence. The Duke of Wellington's armies had no tobacco worth speaking of. If they did not forbid it, the officers were directed to advise their men strongly against its use. This curiously contrasts with the campaigning in South Africa where marches and privations as long and as stern as any suffered by our great-grandfathers were borne with a grumble only when the "smokes" failed the men. No doubt tobacco is a real help to men enduring long labors and receiving little food. It probably acts by quieting cerebration and allowing sleep more easily. Its value seems to be second only to food when long privations and exertions have to be endured.

ILEOSIGMOIDOSTOMY AND LATERAL ENTERO-ENTEROSTOMY FOR CANCER—URETERAL CATHETERISM FOR TUBERCULOSIS—DIFFUSE TRAUMATIC POSTERIOR TIBIAL ANEURISM—ENTERITIS AND ENVIRONMENT—PNEUMOCOCCI AND SORE THROAT—SCARLATINOUS SORE THROAT—PNEUMOCOCCUS OTITIS MEDIA—AMYOTROPHY OF THE NECK IN PULMONARY TUBERCULOSIS—SIMPLE ACHOLURIC JAUNDICE—DIAGNOSIS OF TUBERCULOUS MENINGITIS—SPLENIC DEGENERATION IN TUBERCULOSIS—JAUNDICE AND THE CEREBROSPINAL FLUID—PERMEABILITY OF THE MENINGES IN THEIR TUBERCULOUS INFLAMMATIONS—EFFECT OF COCAINE ON CIRCULATION IN LUMBAR INJECTION.

Tuffier at the Société de Chirurgie de Paris, October 17, 1900, presented in behalf of Charriers (Angers) notes on a case of colic carcinoma of the hepatic flexure with marked and progressive signs of intestinal obstruction and with adhesions preventing anastomosis between the proximal ascending and the distal transverse colon. An artificial anus was not desirable. Therefore ileosigmoidostomy was done. After a few weeks' trouble with fluid stools, the patient made a good recovery.

Quenu stated that he had done this anastomosis even in patients much emaciated, with entirely good results; no appreciable increase in the failure of nutrition could be attributed to

cutting out most of the colic digestion. His conviction is that this operation is far preferable to an artificial anus, whenever it may be done.

Hartmann, at the session of October 24th, resumed the same subject and limited the term *exclusion of the intestine* to cases in which one or both ends of the portion excluded are closed. Thus the exclusion will be closed or open according as there is or is not an artificial anus formed. For his part he considers this latter form of exclusion should not be carried out when it is possible to do a lateral entero-enterostomy. Another crucial point is the selection of the loops for the anastomosis. In general terms the union should be made with the least possible sacrifice of intestinal function. On the other hand, care must be taken not to place the anastomosis too near the cancer. In his own experience the neoplasm had invaded his union. Often the results of this operation are so marvelous that one may be led to doubt the original diagnosis. In one case of his four months after such an apparently absolute cure, the patient succumbed to a general dissemination of the disease.

Albarran, on October 31st, exhibited a kidney removed from a twenty-year-old youth, interesting solely from the early and accurate diagnosis made. The only symptoms were slight lumbar pain and some frequency of micturition. Cystoscopy was entirely negative. Ureteral catheterism showed clear urine from the right side with eighteen grams of urea to the liter, while twelve grams of slightly purulent urine was recovered from the left side. Nephrotomy at the exploration was negative, but on account of the straightforward diagnosis nephrectomy was done, after which a focus at the inferior pole of the organ was found. In the urine from the left kidney were bodies staining with Ziel's solution and probably tubercle bacilli.

Chaput reported a case of diffuse traumatic posterior tibial aneurism, in two large sacs, upper and lower, spontaneous clotting had occurred so that only the proximal opening of the vessel into the aneurism was ligated. Silk was used. Probably it would have been far more prudent to have ligated the distal mouth also.

Rendu, at the Société Médicale des Hopitaux, October 19th, introduced a youth recovered from a biliary fever with hemoglobinuria. A year ago in Madagascar he contracted malaria which progressed so steadily that his return to France was advised. Since then, during the month preceding admission, he showed tertian fever and on reaching the hospital was suddenly attacked with a severe exacerbation of fever and, two days later, by another attack less intense, but accompanied by nausea, vomiting and bloody urine. This hematuria persisted all night and was followed by a jaundice even of the mucosæ, with prostration and almost collapse. Chlorhydrate of quinine hypodermically and quinquina powder by mouth were continued and shortly convalescence ensued. The other features were that the urine contained no blood-corpuscles, but only hemoglobin. Its deposits consisted solely of urobiline and chromogen, but no bile-pigment. Evidently this was icterus hemapheic, as described by Gruber. The spleen during the attack was much enlarged, but had entirely returned to normal dimensions. The purely congestive origin of this condition is difficult to explain.

Renon stated that in the Peter Pavilion of the Necker Hospital from July 15 to October 1, 1900, he had seen nine enteric-fever cases with four deaths among nurslings and mothers. In 1899 the mortality in the same department of the institution reached 57 per cent. These large fatalities were not to be attributed to the severity of the disease, because most of the cases had run a mild course; nor to the lactation of the patients, because of three actively nursing women but one died; nor to the peculiarity of the epidemic because the previous year, 1899, had also shown an excessive death-rate in this pavilion, while in the other departments of the hospital it was about 10 per cent. He concluded that the hygiene surroundings are responsible for the condition and that nurslings usually have a high mortality in typhoid fever. It seems evident that not only are the young children vulnerable to this disease, but that notwithstanding all possible precautions the other intestinal disorders of infancy may act as secondary infection, complicate the process and raise the death-rate.

Bezancon said that most of the bacteria which occur on the pharynx and tonsils during an attack of acute non-diphtheritic angina may be found in the mouth and pharynx in health. Their rôle in the pathogenesis of non-diphtheritic inflammations is very difficult to appreciate by modern bacteriological methods. The frequency with which the pneumococcus is found led him to feel that very likely it could be isolated as a potent factor. In company with Griffon he tried the agglutination test upon them carried out by cultivating the germs in the blood-serum of the patient. The results were conclusive, namely, various degrees of bunching from feeble to intense, although the reaction was ephemeral. Such conclusions were in agreement with the clinical picture and the other bacteriological features of the pneumococcus. Furthermore they tend to show the rôle of this germ in affections previously ascribed entirely to the streptococcus and to substantiate the recent utterances of Widal and himself that these affections should be reclassified and some charged to other organisms. No tests as to the streptococcus could be carried out, as no method of making it agglutinate is yet known.

Variot, at the session of October 26th, rehearsed his results due to the systematic daily examination of 525 children afflicted with scarlatina as to various degrees of sore throats. In 150 patients he found the pharyngotonsillitis develop anywhere from the first day to the conva-

lescence without exudate. In the 375 patients remaining the exudate was at times circumscribed and at times progressing or general. In 62 patients out of 102 in whom the false membrane as an entity existed it was impossible to determine clinically whether the cases were true or false diphtheria and only bacteriological examination gave 30 true and 32 pseudodiphtheritic cases. Bourges and Würtz have stated that any membrane appearing at the end or during the convalescence would be pure diphtheria; but these observations have demonstrated to him that the other often occurs in the same manner, namely, pseudodiphtheria. The author always resorts to free serumtherapy as soon as any membrane appears, because that is the moment when the character of the angina may change and a diphtheria be checked. He also examined 423 children relative to any connection between the febrile cycle, the development of the eruption and the appearance of a pharyngotonsillar exudate. In 295 patients all three developed together and were closely related in the rest of the course, in the other 128 children any two appeared to go hand-in-hand overshadowing the third and quite independent of it. But a high fever always accompanied a frank pharyngitis, while a severe cutaneous lesion might or might not show great elevation of temperature. In no case did he find angina preceded by crops of vesicles as Lasègue has claimed.

Hirtz lately observed a case of pneumococcus otitis media bilateralis with free discharge of pus, but very little or no pain, develop in a woman caring for her husband who was suffering from a severe attack of pneumonia. The diagnosis was established by a bacteriological examination of the pus. The source of infection may have been directly from the sputum which the wife had been in the habit of caring for, probably without thorough washing of the hands. It would be well to direct every one so nursing pneumonia patients to disinfect the hands, mouth and throat most carefully.

Boix pointed out the fact that very early in pulmonary tuberculosis there occurs an atrophy of the neck-muscles which constitutes an early contributive diagnostic sign. As in the examination for the tubercle bacillus its absence does not prove absence of the disease, but its presence is almost proof of it. Careful comparison of the two sides of the neck is necessary and the areas affected are *seriatim* supraclavicular, subclavicular and supraspinous regions. The pathogenesis of this amyotrophy is not clear, but may be compared to those which occur about joints, namely, alterations in the nerve filaments of the pleura carried to the spinal cord, perhaps by pure reflex action, by retrograde degeneration or by reaction at a distance.

Lereboullet, at the November 2d meeting, discussed icterus without choluria. His observations were made jointly with Gilbert. The special type investigated was the *simple*, that is, not accompanied by evident affection of either the liver or bile-passages, very commonly seen especially as an hereditary or family manifestation after a generation afflicted with cirrhosis, chronic choleangitis, cholelithiasis or other hepatic or biliary disease. These hereditary tendencies are marked. The typical symptoms are slow indeterminate invasion, jaundice of the skin, often general sometimes partial, no discoloration of the mucosæ, fatigue, malaise, biliary pigments in the blood-serum but not in the urine, and no appreciable signs in the liver itself. Often one may differentiate irregular secondary symptoms like pruritus, urticaria, xanthelasma, etc. The xanthodermia of Besnier is probably this condition. Again, dyspepsia may characterize the disease or neurasthenia, hysteria, hemorrhagia, especially epistaxis and menorrhagia, both leading to anemia simulating chlorosis (*false chlorosis of icteric origin*). The cause of this disease, which corresponds to the "bilious temperament" of older physicians, probably lies in a more or less chronic infection of the bile-passages, accompanied by a cholemia sufficient to pigment the skin, but not the urine. It is ordinarily of absolutely good prognosis, but possibly in those who are specifically so disposed may lead to lithiasis, cirrhosis and other serious disorders of the liver and its ducts. Strict diet with no milk is the sole treatment.

Widal, Sicard and Ravaut, at the Société de Biologie, October 20th, reported further peculiarities of the cephalorachidian fluid in health and various diseases, especially tuberculous meningitis. The cryoscopic point of the fluid in all acute forms of meningitis, no matter how various, oscillated between the extremes 0.56° C. and 0.75° C., the majority of a total of fifteen patients being between 0.60° C. and 0.65° C. The fluid seems to have a hypertonic tendency toward ordinary serum which shows a freezing-point of 0.56° C. In patients with manifest tuberculous meningitis in eight out of ten examined, the point fell to between 0.48° C. and 0.55° C. This fact may become of great diagnostic value.

Raymond and Hulot said that the injection of raw tuberculin gives only an approximate idea of what occurs in the disease. They enclosed active tubercle bacilli in collodion sacs and laid these in the abdominal cavity of animals. By degrees the toxic products of the germs dialyzed through the sac-wall and set up remote effects. Thus was simulated the condition so often present in the human patient when a tuberculous focus poisons the system without circulating the germs. The kidneys were seen to be in the most marked degeneration, although liver, spleen, pancreas and all the other viscera were affected.

Dominici killed three guinea pigs eighteen weeks after inoculation with tuberculosis and examined the spleens histologically. A general degeneration was found in each which he calls myeloid from its close resemblance to bone-marrow.

Gilbert and Gastaigne on November 3d said that they took the cephalorachidian fluid from eighteen patients with icterus and marked cerebronervous symptoms; in fifteen it was normal; in three it showed yellow color and biliary pigments and salts under the Ginelin and Pettenkofer tests. These patients had the most nervous symptoms. It seems possible, therefore, to deny that these symptoms are entirely due to the changes in the fluid, because they are not always mutually concomitant. Why the bile-substances should affect it in some and not in other cases is difficult to explain, unless we assume that in some conditions the membranes otherwise impermeable become permeable. As to the cause of the nervous symptoms, especially the somnolence, in jaundice we have to accept as formerly the presence of bile-products in the blood.

Widal, Sicard and Monod reported that they have found in the normal patient the meninges impermeable to iodide of potassium, whereas in tuberculous disease of these tissues the salt can be recovered from the cerebrospinal fluid. Hence they affirm that this is a third contributive diagnostic point to distinguish this form from others. The previous two differential facts are a change in the freezing-point of the fluid and a specific leucocytosis, namely, lymphocytosis in tuberculosis and polynuclear neutrophile leucocytosis in cerebrospinal inflammation of the membranes.

Hallion and Tuffier have studied in the dog the effect on circulation of cocaine injected by lumbar puncture. Subcutaneous injection always causes universal vasoconstriction with elevation of pressure. In the spinal canal just the reverse is caused, apparently by paralysis of the plexuses of the abdomen, itself due to the intrameningeal paralysis due to the drug. This nerve-depression can be counteracted by irritation of splanchnic nerves, especially by pressure on the abdomen.

SOCIETY PROCEEDINGS.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held November 12, 1900.

J. Blake White, M.D., in the Chair.

Acute Traumatic Malignancy.—This paper was read by Dr. W. B. Coley. In a paper read before the N. Y. Surgical Society in 1897 he said he had expressed his conviction that a large proportion of cases both of sarcoma and carcinoma were of traumatic origin. In that paper it was said that 27 per cent. of the cases observed by him were directly consequent upon injuries. Further experience had confirmed the view then taken. At his request Dr. C. J. Kane had compiled the statistics of the cases of cancer treated at the German Memorial Hospital during the last three years. From these it appeared that in 63 out of 100 cases the disease followed local injury and in 27 irritation of parts affected, and that in only 10 was there not any history of trauma or irritation.

Dr. Coley then cited a number of cases from his own experience. Among them were the following: Male, aged forty-five years; blacksmith. A kick by a horse, causing a simple fracture of the lower end of the femur, was followed in a short time by sarcoma at the seat of injury. Amputation at the hip-joint was followed by an uneventful recovery.—Male, aged twenty-eight years. Early in January, 1900, he received an injury of the right testicle. There followed a rapid swelling of the part, and the patient was twice tapped for supposed hydrocele. In February he was seen by Dr. Coley, who made the diagnosis of hematocele, with possible sarcoma, and operated. Microscopic examination showed round-celled sarcoma. Afterward the patient entered Dr. B. Farquhar Curtis' service at Bellevue Hospital with an abdominal tumor as large as a man's head, and he died on April 18th. This case was remarkable for its rapidity, as only a little more than three months elapsed between the reception of the injury and the fatal result.—Female, aged forty years. Sarcoma of the breast following a blow. Three operations were performed for successive recurrences.—Male, aged five and a half years. An injury of the groin was followed by a spindle-celled sarcoma, which grew with very great rapidity.—Male, aged eighteen years. A brick, falling three stories, struck on the right deltoid muscle. Round-celled sarcoma of the humerus developed and amputation at the shoulder-joint was performed by Dr. George R. Fowler. Very curiously there was a recurrence of the disease in the other humerus.

Out of 100 patients seen by Dr. Coley since the publication of his first paper, in 40 there was a distinct history of trauma and in 8 of local irritation. In 13 the disease developed within one month, and in 8 of the 13 within one week after the injury. In a total of 270 patients the disease was preceded by trauma in 80, or a little more than 31 per cent. In 11.5 per cent. of the cases the disease occurred within one week after the injury. The subject of acute traumatic malignancy is certainly receiving more and more attention from the profession, and it would seem that the old opinion of the laity that cancer follows injuries really has a substantial basis in fact. Beginning with W. Harrison Cripps, who in 1882 found a traumatic origin in only 7 per cent. of cases, Dr. Coley quoted the statistics of various writers, and said that there was undoubtedly sufficient evidence to show a definite history of trauma in a large proportion of cases. Just how the injury acts is as yet an entirely unsettled matter. Most of the German authorities incline to the view of a constitutional diathesis, predisposing to malignancy. Dr. Coley said that his own opinion had not changed. He still felt con-

vinced that such tumors are infectious, or, in other words, of microparasitic origin. Having referred to their analogies to tuberculosis and osteomyelitis, he said it was reasonable to suppose that in many individuals the cancerous micro-organisms exist in a latent state, and that a local injury or irritation has the effect of arousing them into activity. The main conclusions arrived at were as follows: (1) Trauma is a very important factor in the causation of malignant tumors, and (2) this relation appears to afford considerable support to conclusions as to the infectious nature of their growths.

Dr. B. Farquhar Curtis said it was wise to guard against trusting too implicitly to the statements of patients with reference to antecedent injuries. Thus, in cases of cancer of the breast it was generally very easy to get some sort of a history of trauma, but when definite facts as to the injury were wanted such were often very difficult to obtain. It was certainly true that these injuries were more likely to be followed by sarcoma than by carcinoma. Having referred to a case of osteosarcoma in the clavicle, which was followed by a secondary sarcoma of the rib, he said that all these thickenings occurring after contusions of bones are by no means sarcoma. In addition to the hypotheses mentioned by Dr. Coley he suggested another possible method, namely, the effect of the injury in causing a proliferation of cells, a return in a measure to embryonic conditions. In conclusion he referred to two practical points, *viz.*: (1) The effect of this theory of traumatic causation of malignant disease upon accident insurance and on suits for damages. (2) A great many women have tumors of the breast following some accidental injury by a member of their family, but it is advisable not to express too positive an opinion, as this might add to the trouble and distress already existing.

Dr. Fred. Lange was inclined to accept Dr. Coley's view of the parasitic nature of the disease, and thought that more extended experiments should be carried on for the purpose of establishing or disproving the hypothesis. At the present time there was not enough uniformity among pathologists to permit of positive statements.

Dr. Louis Heitzmann took issue on this point, and said that all the micro-organisms which had from time to time been adduced as the etiological factors in the production of malignant growths had been disproved. To him the return of the cells to an embryonic condition, as referred to by Dr. Curtis, offered a much more satisfactory explanation.

Dr. Coley said that this was a great problem which would require the combined efforts of many observers to solve. The claims put forth by San Felice, Roswell Park, Lephold and others had not been disproved, while, according to Edwin Klebs, the embryonic theory of Cohnheim was no longer tenable.

BOOK REVIEWS.

A Practical Treatise on Medical Diagnosis. For Students and Practitioners. By JOHN H. MUSSER, M.D., Professor of Clinical Medicine in the University of Pennsylvania; Physician to the Philadelphia and the Presbyterian Hospitals; Consulting Physician to the Woman's Hospital of Philadelphia and to the West Philadelphia Hospital for Women. Fourth Edition. Lea Brothers & Co., Philadelphia and New York.

VIEWED from the standpoint of posterity there is no doubt that the present time will be regarded as a notable epoch in the history of medicine and that the last few years will be deemed to have been as productive of real advance as any period of the immediate or more remote past. For, while we cannot, perhaps, point to any single invention or discovery as epoch-making, for example, as the achievements of Jenner in practice, or Laennec in diagnosis, it cannot be disputed that our general attitude toward the recognition and treatment of disease has lately been so markedly modified and the practice of medicine so completely lifted from the domain of empiricism to something at least approaching an exact science that we may justly claim for our day the same deference and gratitude that we accord to the age that gave us vaccination and the stethoscope. But the ability to profit by the work of the investigators who are daily enriching our knowledge in their special departments is to be gained only by a scientific education of a breadth undreamt of by our fathers and the clinician of to-day must not only be a practitioner of medicine in the older sense, but also be an expert microscopist, bacteriologist, pathologist and chemist as well

This increased complexity of the art is being recognized and well met by our medical colleges whose graduates are for the most part turned out equipped to pursue their investigations in any field of scientific inquiry that seems likely to be helpful in solving the problems of daily practice, but there is still the huge class of general practitioners who are too busy to take up postgraduate courses or spend their time culling from the literature the information likely to be of practical value. It is especially for these that this book should be of inestimable value and that it has been appreciated is shown by the appearance of this the fourth edition only six years after the publication of the first. In the author's words, "Instruments and methods of precision, physical, chemical, microscopical and biological, are now so readily at the command of every practitioner that he is legally, as well as morally, bound to exhibit in his diagnosis and treatment a degree of certainty far greater than could formerly have been exacted," and it is precisely the various methods and appliances by which such accuracy is to be attained that are detailed

with a clearness and completeness surely never surpassed in any manual of the sort. The author has combined in a single volume a description of the laboratory methods and technic required, with beautifully clear and logical discussions of the bedside work and physical signs. After an introductory chapter the first part of the book on general diagnosis is divided into the data obtained by inquiry; the data obtained by observation; a full discussion of the examination of that tissue which now bears the *crux* of nearly every difficult diagnosis, *viz.*, the blood; and a section on the morbid processes and their symptomatology. Part II. on special diagnosis considers the nose and larynx; diseases of the lungs and pleuræ; diseases of the heart, the blood-vessels and the mediastinum; diseases of the mouth, fauces, pharynx and esophagus; diseases of the stomach, intestines and peritoneum; diseases of the liver, spleen and pancreas; diseases of the kidneys; and, finally, an admirable section on the diseases of the nervous system which is calculated to do away with much of the feeling of hopeless confusion with which they are usually regarded by the general practitioner. This edition has been completely revised and in part rewritten with the addition of many new illustrations and is in all important particulars so perfect that it is surprising to note how many misprints have been allowed to stand all through the book, such as "otitis" for "ostitis" on page 85, "palpation" for "palpitation" on page 88, "inquiry" for "injury" on page 49, and the omission of the word "not" from the fifth line of page 47, whereby the author's very obvious meaning is exactly reversed; while on page 385 in the very complete list of diseases accompanied by eosinophilia we find no mention of bronchial asthma or the helminthiases. The illustrations throughout are of unequaled beauty and clearness, the elaborate set of plates illustrating the physical signs in disease of the chest and abdomen being of especial interest and value. Indeed, considered from every standpoint, that of subject-matter, style, and mechanical excellence, the work deserves only praise of the highest order, and there is hardly a student or practitioner in the country who would not find it an invaluable reference-book for daily use.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D. Volume III. September, 1900. Philadelphia and New York: Lea Brothers & Co, 1900.

The present volume of "Progressive Medicine" contains the review of the recent literature of Diseases of the Thorax and Its Viscera, by William Ewart, Physician to and Joint Lecturer on Medicine at St. George's Hospital, London; of Diseases of the Skin, by Henry W. Stelwagon, M.D., Clinical Professor of Skin Diseases in Jefferson Medical College, Philadelphia; of Diseases of the Nervous System, by William G. Spiller, M.D., Professor of Neurology in the Philadelphia Polyclinic, and of Obstetrics by Richard C. Norris, M.D., Instructor in Obstetrics in the University of Pennsylvania. The names of the reviewers constitute the best possible guarantee that nothing of practical importance in the recent literature of these subjects has escaped notice.

The article on diseases of the chest comes very opportunely for the season of the year when respiratory affections are most frequent. It is the custom to think that there is practically nothing new in the old subject of thoracic diseases. A glance at the present volume, however, shows that suggestive advances, practical and helpful, are constantly being made. We note in passing typhoid pneumonia, for instance, which has lately been raised to the dignity of an independent symptom-complex. Abram's aids to the diagnosis of pleural friction are interesting. Three maneuvers are practised to bring out the pleuritic murmur: (1) The extended arm is raised to the side of the head; (2) the patient lies on the affected side for one or two minutes and then rises quickly while holding the breath. Friction if present will be intensified owing to closer pleural contact in a collapsed thorax; (3) the intercostal pressure maneuver, the buttoned rod of the phonendoscope fitted into an ordinary chest-piece, is pressed firmly into the intercostal space. Dorsal percussion and percussion of the spine are subjects in which a certain amount of progress has been made quite recently and the advances are of great interest to the practitioner who wishes to be exact in diagnosis. The use of the good old-fashioned poultice has threatened to go out entirely. Certain hints as to its indications and the method of preparation are given in the present volume which show that it still deserves a place in the therapeutic armamentarium.

In the chapter on diseases of the nervous system Dr. Spiller says: "Probably no organic affection of the nervous system is more common or has been better studied than hemiplegia, and yet the subject still offers much opportunity for investigation. Even those who have seen many cases of unilateral paralysis of rapid development find it difficult at times to determine the cause of the paralysis." Dr. Spiller's words are well calculated to encourage more careful study of hemiplegic conditions and are especially suggestive for the general practitioner who sees so many cases of this affection. In the question of the surgical treatment of brain tumor Dr. Spiller calls attention to a case in which operation showed the presence of an infiltrating glioma which could not be removed. The opening in the skull that remained after the operation gave the tumor a chance to expand in its growth until it formed nearly as large an extracranial mass as the man's head. Undoubtedly the relief of intracranial pressure thus afforded saved the patient great pain and prolonged his life.

Dr. Norris in his review of obstetrics begins with an abstract from an article on parturition

among the Eskimos. These women are delivered when alone and at a distance from any habitation. It is considered unclean for them to remain any length of time where the child is born. The mother drags herself at once some distance, often over snow and ice. Despite the rigorous conditions the rate of mortality for both mother and babe compares favorably with the death-rate in more civilized communities. The story surely emphasizes the importance of as little obstetrical interference as possible.

A Dictionary of Medical Science. By Robley Dunglison, M.D., LL.D. Twenty-second Edition. With Appendix, thoroughly Revised and Greatly Enlarged. By Richard J. Dunglison, A.M., M.D. Lea Brothers & Co., Philadelphia and New York.

The Students Medical Dictionary. By George M. Gould, A.M., M.D. Thirteenth Edition. P. Blakiston, Son & Co,, Philadelphia.

The American Illustrated Medical Dictionary. By W. A. Newman Dorland, A.M., M.D. W. B. Saunders & Company, Philadelphia and London.

A deluge in lexicography threatens to overwhelm the medical world. During the past year four or five medical dictionaries have appeared from different publishers.

The veteran Dunglison still leads the van with its twenty-second edition. Gould's dictionary is now in its thirteenth edition, while Dorland's is a new claimant for honor.

The first is the same solid standard work, but with a really valuable appendix that brings it up to the vocabulary of the century, and the last is a work on a more modern plan, well bound and well illustrated.

The only drawback to Dunglison's dictionary is the hybrid nature that arises from keeping old and disused terms in the body of the work, and the newer terms in the appendix; and yet the classification on such a plan makes an interesting comment on the advance of medicine since the main portion of the work was published. As an illustration of the rapidity with which new words are coined to express accurately the advances in science, we note that this twenty-second edition contains fifteen thousand words over and above those in the twenty-first edition published seven years ago. When we remember that five thousand words suffice the average man for polite conversation, and that Shakespeare's vocabulary, the largest in the English language, numbered but fifteen thousand, it is rather appalling to learn that the doctor's word centers must respond to this extra strain.

In the present edition, the subject of bacteriology naturally claims a large proportion of the increase; and so accurately has its terminology been handled that it may be regarded as, for the time being, complete. The recent discoveries in new drugs and chemical combinations have also added a vast number of words in the subject of therapeutics and materia medica. The difficulty of keeping pace with this subject may be appreciated when one remembers that during the last three years twelve hundred new medicines, or compounds have been manufactured and named.

Those who are familiar with Dr. Gould's dictionary will find few changes in the new edition except in the eponymic terms, and those that the last few years have brought into universal use.

The American Illustrated Medical Dictionary by Dorland has the very valuable recommendation of a convenient size. It can be pulled from its shelf and replaced by a wrist movement, involving no particular use of brawn; therefore a man will consult it perhaps twice as often as a dictionary that monopolizes a whole table. Moreover, it has flexible covers, and clear print, with an excellent page arrangement. It is concise in its definitions, but not abridged. It contains all the newest established words of the present, without being cumbered by relics. Its illustrations are excellent, and its tables of tests, staining methods, methods of treatment, etc., will be of value to the busy man, who can in a second lay his hand on any formula he wants.

Text-Book of Practical Medicine. By Dr. W. Gilman Thompson. 8vo. Illustrated. Philadelphia and New York: Lea Brothers & Co.

The title of this new work on medicine challenges attention. It is "Practical Medicine"—not the "Practice of Medicine." It is as if this eminent exponent of rational therapeutics and of scientific dietetics had thus publicly recalled the members of our profession to the first duty of the physician, the cure of the sick.

The work is divided into nine parts. In Part I. three hundred and fifty-six pages are given to a full and up-to-date discussion of infectious diseases. In Part IX. those diseases which cannot be classified either as infectious diseases or as distinctively belonging to any single physiological system, and the effects of poison and of parasites require one hundred and twenty-five pages for their consideration. The intervening parts are given to the systemic diseases. This classification is as good as any and is perhaps the best now possible. To illustrate in how much this classification differs practically from that of quite recent works, it is but necessary to observe that rheumatism is included in the infectious diseases, rheumatoid arthritis is classed with nervous diseases, and gout is treated in Part IX., under the heading of miscellaneous diseases.

In these thousand printed pages the author has presented in vigorous and easily-flowing English the rich harvest of his ripe experience as physician and teacher. There is everywhere ample evidence of accurate observation, profound scholarship and rare good judgment. There is no slighting of accurate and luminous description of the various manifestations of diseases. There is not missed any of the very latest discoveries in the etiology of diseases. There is no minimizing

of the importance of an early and sure diagnosis, and no lack of a complete consideration of the difficulties in diagnosis and of the means by which an accurate diagnosis may be made. There is no "cut and dried" therapy—no list of formulæ properly labeled with the names of the diseases for which they are supposed to be invaluable, but in a direct and most satisfying manner, yet without dogmatism, he has given in sufficient detail the exact method of treatment that has commended itself to his judgment and his experience. We do not need to say of him, as was recently said of an eminent author by a teacher of medicine to his class, "Really, gentlemen, Dr. ——— is a much better physician at the bedside than his book would lead you to suppose."

It is impossible for any work on so great a subject to appear perfect to every reader. Some who will be pleased to see due credit given to the many recent discoverers in the various fields presented by the etiology, diagnosis and therapeutics of infectious diseases will be sorry to miss notice of the work of Williams in developing the use of the fluoroscope in the diagnosis of "incipient" tuberculosis of the lungs; a method which in the hands of experts is so refined that Trudeau considers it even more sure in early diagnosis than is the use of tuberculin. One might wish that the experimental work of that Russian investigator, who has given the most reasonable explanation of the effect of laparotomy in the cure of tubercular peritonitis had been referred to. In the discussion of aneurism, which is exceptionally well done, there is no reference to aneurism of the pulmonary arteries, a condition which, though rare, has been seen by the writer and confirmed by autopsy very recently. Some close student of dietetics will wonder why in the treatment of gout it is recommended "to aid the elimination of waste," while in the treatment of acute gout all the meat broths are prescribed as suitable diet, which, if Masterson and Samby are not wrong, have "a chemical composition closely resembling that of urine" and must, therefore, of a certainty, add to the embarrassment of the eliminating organs. Some will doubtless criticise the early permission of solid food in typhoid fever, and will agree with the writer that it is safer to forbid solid food until the temperature has been normal for ten days. But the criticisms of omission or commission in this work which can be made by the honest reader are very few indeed.

The work of the publishers is commendable. The paper is good if rather thick. The type is large and new and clean-cut, and the judicious use of heavier letters in headings aids materially in rapid reference and in the analysis of each subject. The few illustrations are well done, and are used to show graphically what words cannot so easily convey.

It is confidently predicted that this volume will meet with a hearty reception and that it will still farther enhance the already high opinion the profession has of the author.

A Practical Treatise on Genito-Urinary and Venereal Diseases and Syphilis. By Robert W. Taylor, A.M., M.D., Clinical Professor of Venereal Diseases in the College of Physicians and Surgeons, New York. Lea Brothers & Co., Philadelphia and New York.

In this, which is in reality a thoroughly revised or new edition of Dr. Taylor's well-known book, the author has included the affections of the genito-urinary organs, thus giving to the profession a standard, authoritative, and thoroughly up-to-date work on genito-urinary diseases, venereal diseases and syphilis; the original volume having been completely rewritten and revised throughout.

The author has accomplished the difficult task of presenting these subjects concisely and at the same time of omitting nothing relating to these diseases, which are all of them presented in such a clear, practical and comprehensive manner as to appeal equally to the practitioner, the specialist and student, all of whom will gain much new and useful information from a careful reading of this valuable work. The general arrangement and classification of subjects is a new and happy departure, the writer possessing the faculty of making important conditions and diseases prominent, and of relegating unimportant and infrequently encountered ones to the background.

The various methods of diagnosis and treatment for these affections are given in great detail, and, while distinctly conservative, are thoroughly modern and up to date in every respect, the author basing his observations upon pathological facts, together with a large and scientifically observed clinical experience; so that after a careful reading of these pages the physician will find himself thoroughly equipped to make proper examinations and accurate diagnoses, and also to treat these diseased conditions in a most approved and scientific manner, the author having succeeded in giving this information in an interesting, terse and convincing manner. As a safe and standard guide for workers and students in this department of medicine, Dr. Taylor's latest work, like his older ones, is by far the best as yet published in the English language.

The publishers deserve great praise for the general superiority of the book, as to type, paper and workmanship, and also the excellence of the innumerable illustrations.

A Text-Book of Medical Treatment of Diseases and Symptoms. By Nestor Tirard, M.D., F.R.C.P., Professor of Principles and Practice of Medicine, King's College, London. Lea Brothers & Co., Philadelphia and New York.

In this period of transition and uncertainty regarding the pathology of disease and the consequent skepticism in reference to the efficiency of drugs, it would seem at first glance to require no little courage to father a treatise on medical

treatment. With a proper appreciation, however, of the limited indication for the use of drugs and a realization of the broad application of hygiene and dietetics in the management of patients the field of therapeusis opens and the uncertainties give place to positive conviction and statement. In the book before us it is evident that the author has clearly perceived this aspect of the situation and reckoned with it in the elaboration of his subject. A certain limited number of drugs are specific in their effect, a large number are curative and a still greater number meet and control symptoms. These have discriminating consideration at the hands of our author in the management of disease, or, perhaps we should say, the management of patients, for it is from this standpoint that the book is written.

All the pathologic conditions that flesh is heir to except those strictly surgical are discussed. The author shows a nice appreciation of the limitations of medicine in indicating at what stage certain diseases become surgical and demand operative interference. The discussion of this point in connection with appendicitis, gall-stones, and nephritic colic, indicates a broad and unprejudiced mind.

We could have wished that the author had set forth with greater emphasis his conviction regarding the specific qualities of diphtheria antitoxin. In diphtheritic invasion antitoxin is the "paramount issue," the position of which has been settled as definitely as the gold standard in finance. In tetanus, too, antitoxin is the sheet anchor and the necessity of its early application demands positive, mandatory advice. The chapters on pneumonia and typhoid fever are full of judicious suggestion, safe guides in these critical and trying diseases. The pathology and the complications are discussed sufficiently to indicate the *rationale* of the treatment and so appeal to the intelligence and reasoning faculties of the student rather than to his sheer force of memory.

The style of the author is clear and attractive, and the work of the publishers unassailable. The book will prove of great value to the senior student, the young practitioner, and the general practitioner, and full of suggestion to the learned consultant—an exhaustive yet concise, up-to-date exposition of modern therapeusis.

Obstetrics. A Manual for Students and Practitioners. By David James Evans. Lea Brothers & Co., Philadelphia and New York.

This is one of a series of pocket text-books of that kind which students use so much. The book is divided into ten parts, treating, respectively, of menstruation, pregnancy (normal), obstetric anatomy, mechanism and course of normal labor, management of normal labor, the puerperal state, pathology of pregnancy, pathology of labor, pathology of the puerperal period, and obstetric operations. More space has been given to normal labor and the more frequent complications than to the rarer conditions and more difficult operations. The physiology and pathology of the newborn have been omitted.

The author has presented the subject in a very clear and concise manner and the book cannot fail to be of help to the student. The book is well illustrated, some of the engravings being new and in colors, and printed upon very good paper.

Suggestions to Medical Writers. By George M. Gould, A.M., M.D. Philadelphia: Philadelphia Medical Publishing Company.

It was a good deed of Dr. Gould to write "Suggestions to Medical Writers." The work must have been brought forth in throes, for he can undoubtedly extract much suffering from what gives the ordinary mortal no twinge. Other editors have suffered with him, perhaps not so keenly, because they did not know enough to be pained at so many points, yet sufficiently to pray that the sales of his book may be large, and that the readers may be lured from cover to cover by his little jokes and sprightly terms. There has been need of a medical rhetoric, speller, and complete essay writer; and it is a praiseworthy act to tell contributors so plainly and simply "not to put pen to paper, unless they have something to say," and to "stop when done."

Dr. Gould has the tools of the literary man in his knowledge of the way words and sentences are made, and in his feeling for the right word to express the idea. These tires literary men usually forge for themselves in the workshop of classic literature; but medical men are usually too busy to evolve or borrow a dictum; so they either blurt forth their facts in bold English, or map their ideas in queerly compounded hybrid words borrowed from several languages. We fear that much of Dr. Gould's logical and forceful remarks on medical writing will not be appreciated by contributors who feel that the mechanism of putting an article into decent type devolves upon the editor himself and not upon the creator of the ideas. But if every right-minded physician who started out to write an article would consult this neat, concise little hand-book, he would find out a well-recognized way to abbreviate his citations to describe his cases, to put in charts and illustrations, to write his titles, and insert his foot-notes. He would also get valuable hints on paragraphing, punctuation, and medical spelling, and would incidentally derive much enjoyment from Dr. Gould's strenuous efforts to reform those who will persist in adding *al* to those words ending in *ic*, as *chronic, theoretic*, to make them adjective in form. He says: "In some countries the sheep's tails are so long that they hitch a tiny wagon to each animal, so that it hauls its own caudal extremity. Now, the difference between the sheep and our medical Bo-Peep alpacas is that the words give no valuable wool, and we trail them on the ground behind us, as the ladies do their dress-trains."

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, DECEMBER 15, 1900. NO. 24.

ORIGINAL ARTICLES.

TREATMENT OF INFLUENZA IN CHILDREN.*

BY A. JACOBI, M.D., LL.D.,

OF NEW YORK.

Prophylaxis.—Is there anything like a preventive of influenza? There is, contrary to Berger (Die Infections-Krankheiten, 1896), and others, no infectious disease of equal communicability, either direct or indirect. Under extraordinary circumstances only is there a possibility of avoiding contact. Influenza may be prevented from entering a ship coming from distant ports, or a ship carrying it may be quarantined with rather more theoretical than practical effect. Influenza may be kept out of a monastery or a prison or out of an insane asylum or barracks if there is no intercourse with the rest of the world. It should be kept out of a sanitarium for lung diseases by strict isolation during an epidemic. Indeed, I know of no infectious disease that creates a greater disposition to tuberculosis than influenza. To close a school is unavailing, for the children will contract the disease outside. Expectorated mucus and the result of sneezing should, if possible, be caught and disinfected or destroyed; tools, toys, towels, handkerchiefs, and linen should be treated, *i. e.*, washed and disinfected as in other contagious maladies. To protect the children of a household the patient should be isolated on the upper floor of the house, a demand with which it is impossible to comply in the larger part of our population. Nurslings, if their mothers be sick, should meet them for nursing only. Sick and well children should use disinfectant mouth-washes. I think water slightly acidulated with hydrochloric acid will do best. Drinking-water should also be acidulated in the same manner and may have the same favorable result that is obtained in Asiatic cholera. The irrigation of the nose should be a matter of course in the well and in the sick, for the same reasons that have been urged by myself and very persistently and forcibly by Dr. A. Caillé against and during diphtheria. In this way mucus, which according to Ruhemann catches bacilli as in a net, is removed and the mucous membrane is kept in a healthy condition. In which way the bacillus enters is not entirely clear; if it invades through the mucous membrane like the pathogenous bacilli of tuberculosis or diphtheria or cholera, the more normal the condition of the mucous membrane, the greater is the protection.

Medicinal preventives have been recommended —cod-liver oil by Ollivier; calcium sulphide by Greene; quinine by many. Trials with it made on regiments of soldiers under control in their barracks were equally positive or negative. My experience with preventives is very small. Quinine appeared to cause headache and nausea.

Treatment.—There is no specific for influenza like quinine for malaria or salicylic acid for rheumatism. Innocent muriate of ammonium, also carbonate of potassium, sulphocarbolate of sodium, carbolic acid, ichthyol, and other remedies have been so recommended without the expected success. Thus, rational, hygienic and symptomatic and sustaining medicinal treatment only can be considered. A purgative dose of calomel should be given in order to clear the bowels of microbic and toxic ingesta, the bowels appearing to be the principal point of attack in young children. The patient should be kept in bed, the temperature of the room at 70° F. or more at first, the diet should be scanty and fluid at first—milk, cereals, farinacea, water, lemonades, and broths. The further development of the case will gradually indicate eggs, and perhaps—in a few selected instances only—alcohol in addition to other medicinal stimulants. It is more, however, a slow convalescence that requires it than the course of the disease itself. In this respect it appears to differ somewhat from other infectious diseases, particularly typhoid fever and diphtheria. In the latter the doses of alcohol should be high from the beginning.

If there be a high temperature, cold water is not indicated either as a bath or as a pack. The irritating cough which often requires opiates is rather increased than soothed by it; the characteristic bronchitis of influenza does not bear it; the frequent copious perspiration contraindicates it and so does a weak heart under all circumstances. On the contrary, when there is much muscular pain and restlessness, a warm bath is often beneficial. Hot baths should be avoided unless a very short one in an occasional collapse, and Turkish baths require stronger heart-muscles than we are apt to meet in pronounced cases of influenza. While many common cases of pneumonia, with fair circulation, are apt to do well with cold packs, influenza pneumonias do better with warm ones.

According to Ditmar Finkler of Bonn quinine occupies a front rank.[1] Out of eighty of his patients treated with quinine only three made their appearance at the dispensary a second time, while of those treated with other drugs nearly one-half reappeared twice or more frequently. The favorable action of this drug has been observed by Dujardin-Beaumetz, Teissier, Carrière, Pribram

*Part of a paper read before the Medical Society of the County of New York, November 26, 1900.

and others. Mossé, to abort the disease, administered 1.0-1.25 grams the first day, sometimes also the second. Filatow has also observed its favorable effect especially in children. Others, however, as Eichhorst, Tranjen and Bowie, had no success in the use of this remedy, and Leichtenstern believed that the cases treated with large doses of quinine did worse than those that were not so treated. In the German collective investigation reports some praised quinine as giving brilliant results while others were greatly disappointed in its effects.

Whenever vomiting is severe, stomach feeding is out of the question. The temporary abstinence and afterward rectal alimentation find their indication. Alcohol greatly diluted, peptones, mild salt solutions, and liquid albumins are readily absorbed in the colon which even in the smallest infant, though the fetal length of the sigmoid flexure may be persistent, is made accessible by elevating the hip and moderating the current by not raising the irrigator more than a foot above the anus. Peptonized milk, egg and broths are absorbed in part. Starch in the injection is dextrinized in the colon and thus adds to the nourishment of the enema, but though water alone were injected it would add to the circulating fluid. That is why even a large enema given for the purpose of clearing the bowels may add to nutrition and strength by such of the injected water as is almost invariably retained. Thus, severe vomiting should be treated with refusing to feed through the stomach. The best relief is given by morphine, rarely by ice, either internally or externally. It is not necessary to send morphine down to the stomach; absorption is easy and more readily accomplished in the mouth or throat. A tablet of one milligram may be thrown into the mouth of a child of two or four years, there to be absorbed, or half a drop or one drop of Magendie's solution may be administered in the same manner without dilution.

The indications for the treatment of influenza may be several, the high temperature in many cases, the great discomfort, the restlessness, and the rapidly increasing exhaustion. In the treatment of many fevers it is their causes that require consideration;[2] in others, however, their relations to, and influence on, the body are the main considerations. When the condition of the latter is fair, and no danger is incurred on account of the fever, it should be left alone; when the rise of temperature, however, by itself is injurious, it should be interfered with. At all events the treatment of the symptom "fever" gives us no hope of shortening the disease in which it occurs or of which it forms a part; on the other hand, it is a satisfaction to know that, while we increase the comfort and diminish the immediate dangers, the natural healing process is not disturbed. In this way both the justification and the limitation of the so-called expectant treatment become evident. To allow a high temperature to deteriorate tissues and exhaust the heart or brain, is as injudicious as is the custom of emphasizing the number of degrees of Fahrenheit as the only valuable part of a morbid process. To be satisfied with depressing temperature is a grave mistake, but to allow pneumonia to run its deleterious course of high temperatures unchecked with their full influence on the rapidity of respiration and the action of the heart and on the increase of waste, is equally injudicious.

In their injurious influence on nutrition protracted infectious fevers act, first, like direct losses or like starvation, and, secondly, as immediate poisons. The younger the patient, the greater is the danger from that source. That is why a high temperature without any or with a trifling remission should not be allowed to last, though its immediate effect may not appear very ominous. When a high temperature results in a convulsion we never hesitate to reduce it; here we admit there is a vital indication. Why, then, not reduce it while there is the danger of a possibility or probability of its occurrence? Add to these facts the disposition of the young to inanition which is caused by two main factors. The first is their rapid metabolism, the second and principal one is the relative, almost universal, insufficiency of the young organism.

Moreover, we should not forget that most of our antipyretics are at the same time nervines, analgesics and diaphoretics, thus improving comfort and metabolism. They are surely indicated when bathing is not sufficiently efficient or when baths are contraindicated; in that case they may act as adjuvants, as combinations, and procure sleep and remissions. If I add that there are, however, contraindications to the use of medicinal antipyretics because of possible idiosyncrasies and of the debilitating effects which many of the antipyretic drugs are apt to exhibit, I merely say what all have experienced, and what everybody should remember, *viz.*, that no degree of Fahrenheit and no Greek name of a morbid process are the subjects of our medication, but an individual patient. From these points of view our fever remedies should be judged.

In my paper of 1890[3] I said that acetanilid ought to be preferred among the poor because of its low price, antipyrin mainly where great solubility was required for the purpose of its administration in rectal and subcutaneous injections, and that phenacetin was preferable to either when it could be given by the mouth, because of its less uncomfortable effect on the brain, the heart, and the skin.

This opinion I have to modify to a certain extent, not that I object to what I said of phenacetin, but acetanilid should never have an opportunity to show what good qualities it may have, in the rich or poor. It should not be used at all, under any circumstances, not even in the quack preparations which now and then I know to disfigure the prescriptions of regular practitioners. Being a derivative of anilin, acetanilid is poisonous. Not only has it a sedative or rather paralyzing effect on the central nervous system, but it destroys the blood and causes anemia by changing hematin into methemoglobin, though given

sometimes in small doses. That is what gives rise to cyanosis so often observed, more often than after the administration of any other of our modern analgesics and antifebriles. The poisonous effect is even noticed when the drug is used externally, mainly on the young. Examples of such cases were reported at the meeting of the Philadelphia Pediatric Society, April 11, 1899.

Antipyrin when employed during normal conditions increases the tension of the pulse and blood pressure—therefore it is contraindicated in hemoptysis—and produces perspiration. It works more on the general central nervous system than on the center of circulation, that is why it acts—while being antipyretic—as a sedative and analgesic. But it should not be considered as a nervine, for its action appears to be *ushered in* through the mediation of the blood and blood-vessels. The body temperature begins to decrease within fifteen or twenty minutes after the first dose; to render its antipyretic effect more tangible and persistent, it should be followed by a second within two hours. This rule, however, does not hold good when the drug is given for its sedative or analgesic or for its slight antirheumatic effect. Its general effect is mostly good, but its undesirable effects are many. Otto Seifert[4] quotes eighty authors of note who report disagreeable effects of antipyrin; they were observed in the gastro-intestinal, nervous and circulatory system, in the skin and in the mucous membranes. Phenacetin is dismissed with ten. It resembles acetanilid, but is very much milder in its effects. The transformation into methemoglobin takes place after large doses of several grams only. Half-gram doses for antipyretic, gram doses for analgesic purposes are recommended. The doses to be given to infants and children should be from fifteen milligrams to three centigrams (gr. ¼-½).

Salipyrin, the salicylate of antipyrin, is employed by Finkler. While antipyrin causes perspiration, sometimes excessively so, he reports a case in which hyperidrosis was instantly cured by salipyrin. It should be given in twice the doses of antipyrin, is usually better tolerated than the latter, particularly by neurotic or neuralgic patients, because of the relative absence of accidental effects.

Salophen is extolled by Drewes of Hamburg who prefers it to salicylic acid and to salicylate of sodium, mainly in the nervous form of influenza. Adults took from one to six grams, children from three to five decigrams. Finkler, who quotes him, adds: "I believe that most physicians have arrived at the point where they would not like to be without these preparations in influenza, but it should certainly not be forgotten that reports of this kind have quite frequently been used for advertising purposes."

There is something else that should not be forgotten, *viz.*, that there is hardly a disease which has as great a tendency to cause exhaustion and numerous other nervous symptoms, from languor to heart failure, as influenza. If there be the slightest indication of such a danger, none of the above-mentioned drugs should be given without the addition of a stimulant. That should, according to what I said before, rarely be alcoholic. Caffein preparations are vastly preferable; mainly the salicylate (or benzoate) of sodio-caffein, which, being very soluble and readily absorbed, is almost ideal in its effect. That is why in emergency cases of heart failure its subcutaneous administration may often become indispensable. The use of strychnine is so well understood and so general that I limit myself to merely mentioning it.

To what extent stimulants should be given in the average or in the grave cases depends on the general condition of the patient, and on his medical adviser's knowledge of his former health and his resisting power. It is probable that in most cases some daily doses of sulphate of spartein, five centigrams (gr. 5/6) for a child of two years, will have a favorable effect. The caffein preparation I mentioned may be given in doses of from two to six decigrams (grs. iij-x) daily. When it appears to act as an excitant on the brain, it should be replaced by camphor in daily doses of from one to four decigrams. All these doses, however, should be much increased when strong stimulation is required, and in an emergency subcutaneous injections of the same drugs should be used, caffein being soluble in two parts of water and camphor in four parts of sweet almond oil.

One of the best stimulants, useful in the gravest of all cases which are attended with collapse and heart failure, is sadly overlooked among us, *viz.*, Siberian musk. I know of nothing better in the most urgent of cases. A child of two years should take of the 10 per cent. tincture five to ten minims every half hour until half a dozen or a dozen doses have been taken. Musk, together with large, hot enemata, has led me over many a difficult pass, and I again offer this experience of mine, which now extends over fifty years, as a contribution to your aid in dire distress, always, however, reminding you of the fact that all these measures are not exclusive to influenza, but to all conditions of nerve exhaustion, no matter from what cause.

At last, let me allude to a singular experience which was published ten years ago. I do not know that it has been repeated since.* Goldschmidt[5] reports as follows: "About New Year's, 1890, a lady suffering from influenza landed in Madeira and disseminated the disease in a short time. Two months previously there had been an epidemic of smallpox and numerous vaccinations and revaccinations were performed. Now, it so happened that all those who were successfully vaccinated—112 all told—remained free of influenza. Of 98 who were vaccinated unsuccessfully, only 15 took sick." The author concludes from this experience that successful vaccination is a preventive against influenza. But as yet there is

*In the discussion following the reading of this paper Dr. Holbrook Curtis referred to the internal use of vaccine virus by himself and others. A. J.

not enough known to justify any such conclusion with anything like certainty. Still, it suggests the possibility of a future serotherapy for influenza and its very serious consequences.

THE CLINICAL PICTURE OF EPIDEMIC INFLUENZA.

By GLENTWORTH R. BUTLER, M.D.,

OF BROOKLYN;

ATTENDING PHYSICIAN TO THE METHODIST EPISCOPAL AND BROOKLYN HOSPITALS; CONSULTING PHYSICIAN TO THE BUSHWICK CENTRAL HOSPITAL, BROOKLYN, N. Y.

The subject of this paper, although well worn, is not devoid of interest. The clinical picture of epidemic influenza is a composite—several panels set into a single frame. The name of the disease is itself a misnomer, a considerable proportion of cases exhibiting no catarrhal symptoms referable to the upper air-passages. This fact is in consonance with the modern conception that many of the specific infections may affect the organism as a whole, without necessarily giving rise to certain special and localized lesions, the presence of which was formerly considered a prerequisite to the existence of the disease. Thus, the finding of intestinal ulceration is not essential to the post-mortem diagnosis of typhoid fever, for in this disease there may be a generalized typhoid septicemia, or the brunt of the attack may be borne by the lungs (pneumotyphoid) or the kidneys (nephrotyphoid). So, also, scarlet fever may kill without an eruption; or in lobar pneumonia the systemic infection may be so intense and overwhelming that death takes place in the stage of engorgement and beginning consolidation, or, in the same disease, the general septicemia dwarf into insignificance the pulmonary localization, although life has been sufficiently prolonged to allow ample time for the development of the latter.

As with these, so with influenza. The incidence of the toxin of the influenza bacillus (Pfeiffer's) may fall sometimes upon one, sometimes upon another, organ or system; or after expending its force upon one set may subsequently involve others; or may manifest itself as a general acute toxemia. The symptomatology of the disease is therefore extraordinarily diverse, and for this reason the disease has superseded malaria as a diagnostic scapegoat with the careless and easily satisfied examiner.

In general after an incubation of from one to four days the disease sets in abruptly with chilliness or, in some instances, with a severe rigor. In women recurring syncope is not uncommon. Fever is almost always present, but is extremely variable, ranging from 100° to 105° F. and continuing with irregular remissions for from one to ten days. Recurring chills with high intermittent fever, closely simulating malarial fever of the same type, are not very uncommon; but a blood-examination shows the absence of the plasmodium.

There is, in almost all cases, severe headache and general aching, with a degree of weakness and prostration which, except in the presence of severe complications, is out of all proportion to the apparent cause. Delirium is not uncommon, especially in women, children and neurotic men.

The general symptoms just described are manifested in varying degrees in all cases. Depending upon the special localization of the infection certain varieties of the disease are recognized.

The early symptoms of the *respiratory form*, which is, perhaps, the most common, are those of a severe coryza, followed usually by pharyngitis, laryngotracheitis and bronchitis. Very commonly a careful examination will reveal a slight, patchy pneumonia with scanty physical signs. The cough is apt to be violent and paroxysmal. The occasional extraordinary persistence of the influenzal cough is one of the remarkable features of the disease, and it may prove one of the most difficult problems of the therapeutist. Morphine to narcotism, in addition to a long list of antispasmodics, sprays, and inhalations, has failed to arrest it, even temporarily, in fortunately rare cases. In other instances the general aching and extreme weakness may be the only characteristics which prove an apparently ordinary coryza to be a true influenza.

The *nervous form* of influenza is almost as common as the respiratory form. The fever is slight, but there is atrocious headache, severe pain in the back and limbs, and marked prostration. These may be, and often are, the only symptoms, but in a certain proportion of cases coryza and cough supervene in the course of two or three days. This is a sufficiently frequent occurrence to require a word of forewarning to the patient.

When the spite of the poison is vented upon the stomach and intestines—the *gastro-intestinal form*—there are nausea, vomiting, abdominal pain, and a profuse watery or serous diarrhea. With these symptoms there is extreme prostration, amounting at times to actual collapse. Such cases are luckily not common, but the possibility of their occurrence during an epidemic of the disease should be borne in mind. I recall an experience of a few winters past in which seven members of one family fell ill, one following the other at intervals of two days, with the regularity of the scholastic row of bricks, three with the nervous form, three with the respiratory form, and one with the gastro-intestinal form of the disease—facts which permitted an easy diagnosis in the last case.

Still more rare is the *typhoid* or *febrile variety* of this disease. The fever is of the continued type, with delirium, dry, brown tongue, tympanites and other evidences of the typhoid status. The recurring chills and intermittent type of fever which characterize a certain proportion of cases have already been mentioned.

The portrayal of the disease is incomplete without a reference to its complications, sequelæ, and occasional symptoms.

Bronchopneumonia is the most common of the respiratory complications; the lobar form less so. Pleurisy is not uncommon, but seldom terminates in empyema. Abscess and gangrene of the lung are rare sequelæ. Edema of the lungs may occur, almost invariably as a sequence of pneumonia. Enlargement of the bronchial glands, of which the physical diagnosis is very uncertain, is, perhaps, rather frequent. Indeed the persistent cough of influenza has been attributed with some show of probability to irritative pressure upon the laryngeal nerves by the swollen lymph-nodes.

Certain symptoms or sequelæ belonging to the organs of circulation are very common. The pulse often remains unduly frequent or quickens disproportionately after exertion for long periods subsequent to the attack. Two instances of paroxysmal tachycardia have been noted in personal experience as a consequence of influenza. On the other hand bradycardia may follow. An irregular pulse is not uncommon. Several cases of the so-called influenzal angina pectoris have been of much practical and prognostic interest. Women, usually but not necessarily of the neurotic type, appear to be the principal sufferers. The pain may be very severe, precipitated especially by mental emotion, less often by physical exertion, and the severest attacks may occur at night. The heart action is usually weak and often irregular. All the cases seen, in two of which a diagnosis of true stenocardia had been made by good observers, have recovered in periods varying from six to eighteen months. In all of these the patients were under forty years of age, and there were no physical signs of arterial degeneration. A weak, often dilated heart, without anginal symptoms, is by no means infrequent. Inflammation of the pericardium and endocardium may occur; so also may phlebitis and thrombosis of different vessels.

The nervous system is affected to some extent in all cases. Thus depression of spirits is extremely common, sometimes developing into an actual melancholia; and a persistent insomnia may follow an attack. Active delirium has been noted, and one case of acute mania, which recovered under sanitarium treatment, occurred last winter as a sequel of a grippal bronchopneumonia. Neuralgias are common; migraine less so. Inflammatory diseases of the nervous system may be initiated. Occasionally one sees cases presenting the symptom-group of cerebral meningitis, these symptoms persisting for two or three days and then vanishing. In two instances death occurred after violent meningeal symptoms and the autopsies showed intense cerebral hyperemia, evidently the beginning of an acute encephalitis. In such cases recovery may occur with a resulting hemiplegia or monoplegia; the formation of an abscess of the brain is rare. Much more frequently encountered is some form of neuritis.

Neurasthenia, of a light grade, is, perhaps, the proper term to apply to the prolonged weakness of convalescence from this disease, but it is astonishing to realize the frequency with which a severe and protracted neurasthenia can be traced directly to an attack of influenza, an attack which at the time of its occurrence did not seem to be of especial intensity. In these cases one cannot help acknowledging a special predilection of the influenza toxin for the nervous system, even when allowance is made for the natural inclination to attribute a condition to the most obvious, although not necessarily the most efficient, cause.

The spleen may enlarge acutely as in other acute specific infections. Catarrhal jaundice is a sequel of which several instances have been observed, due usually to a gastroduodenitis arising from the action of the poison upon the mucosa of this part of the intestinal tract, although the jaundice may be purely of the toxemic form.

Acute nephritis is not rare; hematuria and acute congestion without a true nephritis may occur. Conjunctivitis, as a part of a coryza, is frequent, iritis uncommon, and optic neuritis rare. A rather common complication is a suppurative inflammation of the middle ear, followed in an unusual proportion of cases, especially during the winter of 1899-1900, by mastoiditis. In one case the symptoms were so violent and threatening that operation was imperative at the end of forty-eight hours from its inception, and the whole mastoid process was found to be infiltrated with pus. The fever, which at the time of operation was 105.6° F., subsided very gradually, not reaching the normal until two weeks after the surgical interference. Vertigo, sometimes very persistent, and occasionally due to labyrinthine disease, is not infrequently observed. Herpes labialis is very common. Sometimes a diffuse erythema, and possibly purpuric spots, are witnessed.

With reference to the diagnosis it is desirable that in doubtful, or suspected sporadic cases a bacteriological examination of the bronchial or nasal secretions should be made in order to find Pfeiffer's bacillus, which, if present, will declare the disease to be influenza. This examination is not easy and is reliable only when made by an expert. During the existence of an epidemic there is usually no difficulty in making a diagnosis, nor in a sporadic case if the symptoms range themselves under the head of one of the recognized types. The cardinal symptom is the excessive and disproportionate weakness. The disease may require differentiation from the following:

1. *Typhoid Fever.*—Influenza begins suddenly and lacks the regular temperature curve, rose spots, and positive Widal reaction of typhoid fever.

2. *Cerebrospinal Meningitis.* — In certain cases of influenza the sudden onset, headache, backache, delirium, and muscular stiffness may afford a clinical picture exactly like that of cerebrospinal meningitis, and the differential diagnosis must depend upon the bacteriological ex-

amination; in the one case for the Pfeiffer bacillus, in the other for the meningococcus.

3. *Bronchopneumonia.*—If the question arises as to whether a given case of bronchopneumonia is of influenzal origin, a rather peculiar and anomalous combination of physical signs may answer the question in the affirmative, *viz.*, varying degrees of dulness over both chests posteriorly, with weak respiratory murmur, impaired transmission of voice sounds, and a shower of fine and subcrepitant râles at the end of a deep inspiration, heard in scattered areas or patches, especially at the bases. The combination is probably indicative of a mixture of bronchopneumonic spots and collapsed lobules.

As to prognosis, recovery occurs in the large majority of cases. The mortality varies from ½ to 2 per cent., and is generally due to a complicating severe pneumonia, especially when affecting the very young or the aged.

INFLUENZA AND THE NERVOUS SYSTEM.

By J. M. MOSHER, M.D.,
OF ALBANY, N. Y.

THE numerous affections of all tissues during or following attacks of epidemic influenza suggest either invasion by a most ubiquitous poison, or lowering of the general resistance to the detriment of vulnerable parts. The specific cause of the disease was established by Pfeiffer[1] in the discovery of the influenza bacillus in 1892, and the relations of this bacillus to the multitude of conditions due to the infection have since been abundantly investigated. The almost universal presence of the organism in the secretions of the air-passages indicates clearly its point of contact and favorable culture-ground, and efforts to locate it in other regions have been only occasionally successful. Canon[2] claims to have isolated Pfeiffer's bacillus from the blood, Heryng[3] reports its discovery in the blood from the spleen; Cornil and Durante[4] report a case of meningitis, in which the influenza bacillus was the only apparent cause of the pus in the pia mater; their observations have been confirmed by Eugene Fränkel,[5] and Pfuhl[6] has found the organism in the pus from brain abscesses, and in the cerebrospinal fluid of the lateral ventricles. Pfeiffer himself reports its presence in the lungs, and in sections of tissues found it in the veins, and was able to cultivate colonies from the spleen and kidneys. Krusc[7] regards this general distribution with some doubt. He finds Pfeiffer's bacillus most particularly in the secretions of the respiratory tract (nose and bronchi), and frequently, perhaps even regularly, in certain parts of the lungs, but hesitates to accept statements showing its prevalence in inner organs, especially those of the central nervous system. He acknowledges that the influenza bacillus may be present in these organs, but believes that when they appear to be the chief seat of the disease, there is probably some other hidden localization of the bacillus, as in the accessory nasal cavities, or middle ear, from which its toxin may take its origin. He concludes that influenza is an infection localized in the air-passages, and that the extraordinary general symptoms are due to the formation by the organism of a very powerful poison. Griffiths and Ladell[8] have extracted from the urine of influenza patients a poisonous ptomain, which caused in animals high fever and death in eight hours, and Hood[9] reports similar results of observations carried out by himself.

These reports are of value as confirming the clinical evidences of the virulence of the influenza toxin. With the exception of the few cases in which the bacillus has been thought to exist in other organs than the respiratory tract, the symptoms have been ascribable to the bacterial products, and these have exerted their malignant influence most directly and severely upon the nervous system. The invariability of the nervous manifestations, even with predominating symptoms in other than nervous organs, has been universally noted. Thus Heidenreich,[10] writing during the pandemic of 1830-'33, declared epidemic influenza to be "an affection of the ganglia, with irritation of the mucous membranes;" Leichtenstern,[11] in his observations upon the pandemic of recent years, reiterates, "There is no doubt that the influenza toxins are severe nerve-poisons, and incite inflammatory and degenerative processes, especially in the peripheral nerves, similar to other bacterial toxins and poisons (alcohol, lead, mercury, etc.);" Berkley[12] states that the "toxin of influenza seems to fall with especial stress upon the central nervous system;" A. Schmitz[13] defined influenza as "in the first line an epidemic nervous disease;" Sell[14] as "infectious neurasthenia;" Wilks[15] regards the "nerve disturbances as the very essence of the complaint," and Althaus[16] goes so far as to claim the "bulb as the portion of the nervous system affected." Draper[17] writes that "the cause of the disease is one which spends its force primarily and directly upon the nervous system," and directs attention to the frequent occurrence of relapse, which "is more severe and accompanied by more serious lesions than the original attack."

In the absence of bacteriological proofs, which are not always obtainable, a certain symptom-complex is accepted as pathognomonic, and the diagnosis may be decided by the epidemic character of the disease, and, in the individual case, by "the sudden invasion with chill and high initial fever, the extremely *prostratio virium*, the intensity of the nervous symptoms, and the sometimes exclusively nervous character of the disease, without respiratory symptoms. (Leichtenstern *l. c.*) It may be added that mild attacks occur without the initial febrile invasion, in which the *prostratio virium* is far more severe than that usually associated with infectious processes. In no other toxic disease, except tetanus, is there such disproportionate involvement of the nervous system. This is shown by lassitude, weakness

and mental depression, and is not infrequently followed by one or more complications, as cough, bronchitis, pneumonia, meningitis, anorexia, diarrhea, nephritis, which have given rise to the misleading classification of the disease into the "respiratory," "nervous," "digestive," "circulatory" and "genito-urinary" forms.

Influenza may consequently be defined to be an acute infectious disease, caused by a specific bacillus, cultivated in the respiratory tract, the toxin of which possesses an especial affinity for the nervous system.

Practically every known form of nervous disease has been attributed to influenza. In many cases a previously existing or quiescent malady has been lighted into activity, and instances of severe degenerative lesions of the nervous system, as paralysis agitans, disseminated sclerosis, system diseases of the spinal cord, general paralysis and exophthalmic goiter, may be explained in this way.

The undoubted and unquestioned nervous conditions due to influenza may be divided into two classes: First, those accompanying the invasion of the disease, and appearing as its initial symptom; and, second, those following as sequelæ or complications.

The nervous symptoms accompanying the attack may be manifested in the peripheral nerves, both cranial and spinal, or the central nervous system. An almost invariable symptom of the invasion is severe neuralgic headache, generally most pronounced over the frontal region, and involving the eyes, causing the tearing or aching pain in the bulbs which is particularly characteristic of the disease. Second in frequency only to the cephalic pain are the neuralgias in the limbs and back and intercostal spaces. Gowers[18] regards the pains in the back and limbs as originating in the fibrous tissues, and compares them with "fibrous rheumatism." The lumbago and sacral inflammation may extend to the sciatic nerve, giving rise to perineuritic sciatica. Neuralgias in the distribution of one or more branches of the trigeminus nerve are common, usually showing points of exquisite tenderness on pressure. Other peripheral pains of most varied character have been noted, varying from transient discomfort to neuritic seizures lasting several weeks, and attacking individual nerves or groups, often of asymmetric and unusual distribution. Thus one patient, while dressing in the morning, having had no prodromata, experienced an excruciating pain in the right shoulder, at the same time became chilly, feverish, dizzy, and was prostrated. The limb was not moved without great suffering and remained helpless for several weeks. During convalescence it was one inch longer that its fellow (the scapular muscles). Joffroy[19] reports a case in which neuralgia in the arm and shoulder was followed by atrophy of the deltoid, supraspinatus, infraspinatus, pectoralis and biceps; Brosset[20] cites a case presenting paralysis of all four extremities, and Leyden[21] reports a case of Landry's paralysis, beginning with the "typical picture of polyneuritis, and becoming dangerous by ascending." In his case the peronæi, right radial and root of the recurrens showed neuritic atrophy, and there were microscopic lesions in the cord.

The post-influenzal symptoms on the part of the peripheral nerves are even more bizarre than those accompanying the febrile attack. These may be the effect of an originally severe lesion, in which more than a functional disturbance must be assumed, as a greater or less degree of neuritis. Leichtenstern (*l. c.*) summarizes the literature to 1896, which includes cases of palatal and pharyngeal palsy, paralyses of the extrinsic and intrinsic ocular muscles, singly and in various combinations, unilateral or symmetrical; hypoglossal and facial paralysis, lingual hemiatrophy, atrophic paralysis of the shoulder, chest and limbs, including affections of the deltoid, supraspinatus, infraspinatus, trapezius, serratus magnus, pectorals, and the musculature of the distribution of the radial, ulnar, median, peronæal and crural nerves. Von Rad[22] also reports a case of pure serratus paralysis following influenza. Oppenheimer[23] reports three case of bradycardia, in which the pulse-rate became forty, forty-eight and forty-five, respectively. He writes that he has "not the least doubt that the *pulsus rarus* is due to the immediate action on the pneumogastric nerve or the ganglia of the heart by the influenza toxins." The writer has also observed a patient showing an abnormally low pulse-rate, varying from sixty to forty-four, and also a case with pronounced cardiac arhythmia. Sansom[24] describes cases of tachycardia, with or without irregular action of the heart, and has observed palpitation, flutterings, flushings, perspirations, faintness and tremors, together with paroxysmal dyspepsia and flatulence, nausea, gastralgia and diarrhea—attacks to which he has applied the suggestive name of "vagus storms."

Such a "storm" was exhibited in the following case, showing a most remarkable grouping, in which temporary Cheyne-Stokes breathing was complicated by involvement in succession of the sensory and mixed cranial nerves of the right side—the first, second, fifth, eighth, ninth and tenth—the motor series remaining intact.

The patient was a gentlewoman, aged about forty years, widowed, a school teacher, who for several years had been under both medical and surgical treatment for irregular lesions, neuralgic and osseus, attributed to specific disease. During the second week in March, 1899, she was prostrated by the characteristic febrile movement and pain of influenza, which was then prevalent. On March 21st she was much improved, free from pain, and appeared to have entered upon convalescence. During the following morning she became greatly exhausted, had dyspnea and complained of pain and numbness over the entire right half of the cranium, stating that the affected area was clearly defined by a line drawn through the middle of the face and head. This condition became more pronounced during the day, in the

evening there was difficulty in swallowing, and she stated that the right side of the head "felt as if it belonged to another person." Examination revealed in the affected region analgesia and partial anesthesia, tenderness at all of the trigeminal points, puffiness of the eyelids and face, distention of the veins and deviation of the lower jaw to the left upon opening of the mouth, with paresis of the right masseter. The temperature was 100° F. On the 23d of March further examination showed the hearing of the right side to be lost, both externally and by bone conduction, and entirely normal on the left. On the 24th of March there was absence of the sense of smell and tactile sense of the right nostril, the test being made with paregoric and camphor; inspiration was deeper and fuller on the right half of the thorax than on the left; the right eyelids were edematous and the supraorbital region was tender. The eyeballs moved freely in all directions. There was some difficulty in reading, but the fingers were counted correctly, and no affection of sight could be determined. At eight o'clock in the evening the patient became extremely restless and complained that she could not lie upon the right side, which had hitherto been the easiest position. The respirations numbered thirty-six, and the expansion of the left side was greater than that of the right. She spoke of a "queer, drawing" sensation of the right side of the neck and a "peculiar sound" about the ear. Hearing on this side was still absent. She also complained of a "tugging" sensation from the epigastrium to the back, and while the examination was in progress, a plainly defined rectus spasm was observed, followed, a few minutes later, by irregular, sharp, clonic contractions of the muscles of the trunk and neck of the right side, and finally of the right upper extremity. The temperature was normal, pulse 100. At this time the respirations became irregular, and closely approximated the Cheyne-Stokes rhythm. Photophobia was marked, there was temporary stupor, and a convulsion seemed imminent, but the crisis was promptly relieved by a subcutaneous injection of morphine. On the following morning the patient was greatly improved, able to take nourishment, stronger and free from pain, and two days later convalescence had begun. Slight numbness and defective hearing continued for several days, but complete recovery followed.

Bristowe[25] and Preston[26] report numerous cases of labial herpes in epidemics at a school for girls and on board a training-ship, respectively; G. Finzi and Camillo Moglia[27] observed herpes zoster, and Luigi Pennetti[28] reports a case of bilateral zoster.

The effects of influenza upon the central nervous system may be immediate or sequential. The immediate effect, manifested as great nervous prostration, has already been mentioned. Gross acute lesions of the brain and cord have been noted. Geill[29] states that "at autopsies of cases dying from the influenza poison the central nervous system is always found much congested." Oppenheim[30] mentions the deceptive attacks of hemiplegia, monoplegia, aphasia, etc., following infectious diseases, and especially influenza, which, after a longer or shorter time, disappear. Meningitis, simple, purulent and hemorrhagic, has been several times recorded, and a severe form of the invasion of the fever, resembling meningitis, and terminating promptly in recovery has been recorded by the French as "pseudo-meningitis grippalis."

The following case may be cited as showing the confusing character of the nervous symptoms of influenza and the great possibilities for error.

The patient, a schoolgirl, fourteen years of age, was received at the St. Lawrence State Hospital on December 28, 1893. The delirium had been prolonged and severe and resulted in the diagnosis of insanity and the subsequent commitment. In the institution the meningeal origin of the symptoms was at once recognized, but the lesion was supposed to be tuberculous, a supposition which appeared justified by the pulmonary signs. The eventual restoration of the patient to complete health necessitated a revision of the diagnosis, which was then decided to be "grip pneumonia and meningitis." When admitted to the Hospital the patient was said to have been insane for two months. She was in a cataleptic state, with irregularly occurring local and general spasms, and complete mental and physical helplessness. At the preliminary examination paraplegia, ophthalmoplegia, retraction of the head and of the abdomen, rigidity, general cutaneous hyperesthesia and *tache cérébrale*, with distinct dermographia, were the predominating symptoms. She remained in a critical condition and during the month following there was a marked febrile movement, but with occasional periods of improvement in which she exercised some control of the voluntary muscles. On January 10, 1894, examination of the chest showed areas of dulness at both apices, posteriorly, with general diminution in resonance, universal bronchovesicular breathing, coarse, dry rhonchi, and occasional sibilants, indiscriminately distributed through the lungs. A few days later acute decubitus developed over the trochanters of both sides, and clearly punched, sloughing ulcers, extending to the bone, resulted. On February 19th the high-pitched percussion note, with dulness, was elicited as before, and the sibilant râles continued, as did the bronchial quality of the respiration. There was some improvement in the general condition at this time, and the ulcers of the thigh began to heal. In March the meningeal and pulmonary symptoms had disappeared, and the patient began to rally from the extreme helplessness. Her mind was clear and she began to use her limbs. In April she was able to move about, gained in weight, convalesced rapidly, and early in June she was discharged from the Hospital, entirely recovered.

Of the acute hemorrhagic meningitis in the etiology of which influenza is especially prominent, Strumpell[31] writes: "These cases are ush-

ered in by most sudden and severe cerebral symptoms, and with high fever pass quickly to a fatal termination. The autopsy reveals, generally in one hemisphere only, numerous hemorrhagic encephalitic foci."

Among the functional disturbances of the nervous system due to influenza, hysteria and neurasthenia have frequently occurred. A liberal interpretation of the neurasthenic symptom-complex permits this condition to represent the postinfluenzal vital depression. Gowers[32] graphically describes this as follows: "It is an intense feeling of inertia. Every action, physical and mental, requires an effort of the will to initiate and maintain it that is almost painful. . . . In perhaps the majority it is only after some months that the natural freedom of untrammeled effort is regained." Neurasthenic states, rapid fatigue on exertion, lassitude, loss of the faculty of mental concentration, follow naturally the initial nervous depression. In many cases, under prompt treatment, these conditions improve in a comparatively short time, but others continue for months ordinarily associated with melancholy or hypochondriasis.

The psychoses of influenza also play an important part in its record of debility. Leichtenstern (*l. c.*) assumes that short and sharp attacks of mental derangement may be regarded as a prolonged and atypical manifestation of the initial delirium, generally occurring in patients of good heredity, while the prolonged attacks of insanity probably indicate a predisposition.

Analysis of the causes of insanity alleged upon admissions to institutions for the insane shows that the number of cases attributed to influenza reached its maximum several years after the pandemic of 1889-90. Thus, no patients whose insanity originated in influenza were admitted to the Pennsylvania Hospital for the Insane until the year ending March, 1892, when nine were received. To the New York State Hospitals for the Insane, six postgrippal commitments were made in 1890, in a total of 1942 admissions, and in 1892, sixty-four were received in a total of 2637 admissions, or two and a half per cent., the number remaining fairly constant for the succeeding years. Unfortunately for comparison, statistics are not given as to the grafting of insanity upon other infectious diseases, but its occurrence following typhoid fever and pneumonia is known to be infrequent.

It is shown by these figures that some other factors than the poison of the disease must be operative, and these are to be found in the mental and physical prostration following the disease, which offer a suitable basis for the development of insanity in susceptible subjects. Chapin[33] believes that "it is not established or probable that insanity can arise directly from zymotic influences, but it does happen that whatever causes operate to depress vital force or lower the standard of bodily health, diminish the power of resistance, and the weaker organs are the first to show failure." He also directs attention to the disastrous moral effect upon the community of "a sudden and wide-spread epidemic, which leaves an impress directly and remotely upon the general health." Régis[34] emphasizes the hereditary predisposition. Clouston[35] writes that "the poison of influenza destroyed the cortical energy to a much larger extent than any of the continued fevers or zymotics, and its effects on the mental condition of Europe during the years of its prevalence far exceeded in destructive powers all those diseases put together. It left the mental and nervous tone of Europe lower by some degrees than it found it." Wernicke[36] places influenza as the type of acute diseases in which the nutrition and general strength are rapidly reduced. Jutrosinski[37] notes the immoderate use of depressing drugs, as antipyrin and antifebrin, as a contributory cause of the influenzal insanity.

All forms of insanity have been attributed to influenza, but statements as to the organic-degenerative types, especially those of insidious beginning, as general paralysis and the senile insanities, must be accepted with caution, as an already existing or threatening condition may have been accentuated. The deleterious and often fatal effect of the disease in old age has been noted, both within and without hospitals for the insane. The general experience has been summed up by Draper (*l. c.*), who writes: "Its most serious results have been observed in persons of advanced years and in those enfeebled by previous disease or intemperate habits."

The prevailing form of postinfluenzal insanity has been melancholia, not infrequently with a pronounced hypochondriacal element. This has been accentuated by active disturbances of the senses, with delusions, giving rise to a state of hallucinatory confusion, and in more severe cases by acute delirium. Maniacal states have been common, but much less frequent than melancholy. With the exception of a peculiar group of cases simulating general paralysis, cited by Hack Tuke,[38] there has been little pathognomonic to differentiate the postgrippal psychoses from similar states due to other causes. The prognosis in postinfluenzal mental maladies is generally hopeful. As a complication in existing insanity influenza has had many results. In general its effects may be regarded as commensurate with the resisting power of the patient. As an agent promoting recovery from insanity, a not uncommon result of intercurrent febrile affections in institutions for the insane, influenza has not been effective. Metz[39] alone reports an instance in which insanity was favorably influenced. His patient, who had been the victim of persecutory ideas for two years, was prostrated by influenza on January 13th; on the 17th, wrote a coherent letter, and on February 9th, following, was discharged from the institution, recovered.

From what has been written the following conclusions may be derived:

1. The infection of influenza produces a toxin, which has a severe and selective action upon the nervous system.

2. The immediate effects of this toxin are shown in affections of the peripheral nerves and the cerebrospinal centers.

3. The remote effects are manifested in lowered tone of the nervous system, predisposing to other diseases.

4. These ensuing diseases arise in weakened or predisposed organs, giving rise to the different classes of "respiratory," "alimentary," "genito-urinary," and "circulatory" forms of influenza.

5. Postinfluenzal insanities are also a complication of the postinfluenzal states of nervous debility, in patients mentally predisposed.

6. The postinfluenzal insanities are not essentially different from other insanities due to vital depression.

7. The prognosis of influenzal affections is generally good, under proper management.

8. Exception to this is in influenzal affections arising during the course of other severe diseases, as pneumonia and general paralysis, and during senility complicated by mental or physical deterioration.

Addendum.

Table showing the total number of admissions and the admissions attributed to influenza in the Pennsylvania Hospital for the Insane (private), and in the New York State Hospitals (public), from 1890.

THE BACTERIOLOGY OF THE INFLUENZA BACILLUS.

By AUGUST JEROME LARTIGAU, M.D.,

OF NEW YORK.

NOTWITHSTANDING the many bacterial investigations carried out (1889-92) for the purpose of determining the microbic factor concerned in the production of influenza, it was not until 1892, after the great epidemic, that studies revealed any micro-organism which could seriously be regarded of etiological significance. In the early part of that year Pfeiffer[1] found a very small hitherto undescribed bacillus which at least in some measure conformed to the requirements of specificity. Almost simultaneously appeared the papers of Canon and Kitasato describing the same micro-organism. Later studies have abundantly confirmed the observations of this first investigator. Whilst the evidence at hand does not fully fulfil the postulates of Koch, the fact that it is found almost only in cases of influenza, and that its presence corresponds to the course of the disease, certainly warrants the belief of such a relationship.

When examined either from exudates or cultures the bacillus of influenza appears as an extremely small, slender, non-motile bacillus, whose length scarcely exceeds its breadth by two or three times. The bacilli may be stained by almost any of the basic aniline dyes which they take up rather feebly and irregularly; the poles are usually more deeply colored than the middle parts, thus often giving the appearance of diplococci. In the writer's experience carbol-fuchsin or Löffler's methylene blue has given best results.

The organisms are readily decolorized by Gram's stain, although Kamen states that when influenza bacilli are grown in an atmosphere of hydrogen they often are quite resistant to decolorization by this method.

Although the morphological features of the organism appear quite constant, it is of interest to note the observations of atypical forms by Grassberger.[2] In cultures showing involution forms he was able to study long filamentous types with or without branching and sometimes with bulbous extremities. Lartigau has also seen forms somewhat like this in cultures subjected to somewhat higher temperatures than 37° C.

The facility with which the bacillus influenzæ is destroyed is a matter of much practical importance. Outside the body it has been found very susceptible to injurious influences, such as drying and suspension in unfavorable media. Drying seems to exercise a particularly destructive action; thus Pfeiffer found that bacilli dried for twenty hours were killed; or sputum which had been dried for two days gave no cultures. In ordinary water the life history is also very short. Suspension in such a fluid usually caused their death within two days, whereas in bouillon they may retain their vitality up to two weeks.

From observations of this kind it has been generally assumed that the extracorporeal existence of the influenza bacillus must be very short, and that infection probably takes place by means of the freshly contaminated secretions. As to this being the only method, we are less certain. In this connection the observations of Kaufman[3] are of the greatest interest. As a result of numerous examinations of the dust of telephone-receivers he was able to find bacilli of influenza many times. This is the only observation of this kind that we know of in which these germs have been found outside of the body or its fresh secretions.

Heat and chemical influences react very readily upon this bacillus. Exposure to a temperature of 60° C. certainly destroys it in five minutes; higher temperatures act much more rapidly. Immersion for ten minutes in 1-1000 bichloride of mercury solution, or for thirty minutes in 1-100 carbolic acid, kills it.

The cultural side of the subject for a certain time presented difficulties. Pure cultures may, however, be obtained on the surface of solid media previously smeared with a small amount of blood, either of human or animal derivation. Agar-agar (with or without the addition of glucose or glycerin) and blood-serum give the best results. Experience has shown that the value of adding blood resides in the blood coloring-matter, for the addition of hemoglobin alone acts equally well. Nasstinkoff, on the other hand, substitutes the yolk of egg for the blood and claims satisfactory results. Kruse recommends the use of agar plates covered with rabbit's or pigeon's blood, upon which the infected material is spread with a platinum brush.

The best cultivations occur at body temperature; although it is stated that no growth can be obtained below 28° C., the author has found this possible by gradually cultivating the influenza bacillus at diminishing temperatures. According to Pfeiffer, growth does not take place in the absence of oxygen, and only very slightly in the depths of stabs. Kamen, however, has grown the organism in hydrogen. When thus cultivated he found that they live for three weeks, whereas they usually die within ten or fourteen days when grown exposed to the air. Whilst able to obtain some growth under anaerobic conditions the author has not noted the differences in viability studied by Kamen.

Meunier,[4] as did Grassberger before him, pointed out that the presence of the staphylococcus pyogenes aureus exercises a most favorable influence on the development of the bacillus influenzæ in cultures, not only as regards abundancy, but also seems to stimulate growth activity. Several trials under these conditions have convinced the author of the accuracy of the observations. This, of course, has been noted for other bacteria also.

At the body temperature colonies develop at the end of twenty-four or forty-eight hours and appear as extremely small hyaline droplets, clear as water, often only detectable with a lens. The older colonies sometimes have a yellowish or brownish center, supposedly due to absorption of the coloring-matter of the medium. Kitasato makes it a special point to insist that the colonies are never confluent; as a rule, this is certainly so, but occasionally one notes confluence of two or more colonies. In broth the growth is less abundant; at the end of forty-eight hours white particles are seen on the surface which after a time sink forming the so-called "woolly" precipitate.

Up to the present times studies of the experimental infections with the influenza bacillus have really not been very numerous. It has been clearly shown that under natural conditions influenza probably does not occur in the lower animals. But our knowledge of the experimental side is sufficient to show that a series of phenomena may be induced in animals by the introduction of living and dead bacilli in some respects like those observed in human beings; the analogy is, however, by no means so close as certain experimenters would have us believe. Pfeiffer by injecting living cultures into the lungs of monkeys was able to induce a condition of fever of remittent type. Somewhat similar results were obtained by smearing the uninjured mucous membrane of the nose with a pure culture. In another case in which large quantities of the germs were thrown into the upper respiratory passages, marked prostration and high fever occurred; finally, the animal died at the end of twenty-four hours. There was little evidence of multiplication of the bacilli; the effects were evidently largely due to toxins contained in the bodies of the bacteria. In the case of rabbits, intravenous inoculations of living cultures produce dyspnea, muscular weakness, and fever, but the bacilli very rapidly disappear from the body. Similar effects have been incited by the injection of dead bacilli.

The results of these experiments led Pfeiffer to conclude that influenza was largely a toxic process arising from the absorption of poisonous substances within the bacterial protoplasm. This view has been further extended by the studies of Cantani, and Delius and Krolle.

Attempts to produce immunity in animals have been followed by almost uniformly negative results. Studying the action of the influenza toxin by intracranial injections Cantani added nothing to our knowledge in so far as immunization is concerned. The more recent investigations of Delius and Krolle[5] were somewhat more encouraging, but on the whole negative. Increasing doses of culture within the peritoneum enabled greater resistance, but large doses were invariably fatal. And this is more or less in harmony with clinical observation which shows that instead of immunity after an attack, the individual is really as susceptible as before if not more so.

The distribution of the influenza bacillus within the body is of great interest. In ordinary cases it has been found in the bronchial exudate and nasal secretions in considerable numbers. In typical acute cases it is often present in almost pure culture in the purulent greenish-yellow bronchial exudate. Kamen succeeded in finding it in every one of the hundred cases he examined. At first the bacilli are free, often in clumps, but as the disease advances one sees them more often within the protoplasm of leucocytes. Toward the end the large proportion of them have this distribution. It is stated that as the number of bacilli decreases the staining becomes less sharp and involution forms are apt to appear.

In the epidemic of 1898 Wassermann[6] says that in influenza cases with pneumonia the influenza bacilli were scanty and disappeared very soon; and Clemens[7] has again spoken of the relative rarity of cases in which influenza bacilli may now be demonstrated.

It is a matter of some importance that it be clearly understood that the influenza bacillus may persist in the sputum for weeks after abatement of the symptoms. Elmassian[8] goes so far as to say that it may exist in the respiratory tract as a saprophyte. Other organisms, especially pneumococci and streptococci are often associated with the influenza bacilli, either in acute cases or in chronic lesions of the lungs. Pfeiffer has shown that the influenza bacillus may be found many months in association with chronic diseases of the lungs, at times producing exacerbations. Finkler has observed this tendency among consumptives. Williams[9] in the examination of washed sputa in cases of pulmonary tuberculosis has also found abundant influenza bacilli when no influenza was known to be present in New York. Under appropriate conditions, we have then almost at all times the excitant with which to start an epidemic.

The inflammation of the lung sometimes extends to the pleura; when this has happened the influenza bacillus has occasionally been found in the pleural exudate. But the action of this organism is by no means limited to the respiratory system. Indeed, it has been found in the pericardium (Hogersted), endocardium by Flexner and Austin and in the central nervous system by Pfuhl and Walter, and Cornil and Durante. Pfuhl believes that meningeal infections occur through the roof of the nasal cavity. Haedke has described an interesting case of meningitis and epidural abscess secondary to otitis media in which influenza bacilli were found in the pus from the ear and mininges. The bacillus has also been found in uncomplicated middle-ear disease by Bulling, Pfeiffer, and the writer.

Notwithstanding the statement of Canon that the bacilli may frequently be found in the circulating blood, the opinion of most observers leans the other way. Klein succeeded in finding them in only six out of 43 cases; and Pfuhl obtained it once out of six cases. Slawyk has reported a most interesting case of general infection with multiple localizations in the joints (hands, foot, knee) and meninges.

Turning to the side of diagnosis, one readily from the first appreciates certain difficulties in the application of the bacterial method along practical lines. Within certain limits an early diagnosis may often be made by a mere microscopical examination without resorting to cultures. If a specimen of sputum should contain an almost pure culture of very minute bacilli which take the stain faintly compared with the other bacteria present and which are decolorized by Gram's method, it may be assumed that the case is one of influenza. When other bacteria are present the diagnosis becomes more difficult; cultures will usually then be required. In order to insure success the sputum should be collected with care. The mouth is first washed with sterile water, the sputum placed in sterile dishes, and the culture prepared on media covered with blood. The morning sputum is most satisfactory. Wynekoop, of Chicago, who has given the bacteriological side of the subject much attention, uses a swab to procure some of the infected mucus or exudate from the pharynx, tonsils and bronchi of the patients. The swab is then rubbed on solidified serum containing hemoglobin. The staining procedure is much the same as that employed for microscopic diagnosis of diphtheria. Smears are made on coverglasses by means of the swab. The smear is then stained by carbol-fuchsin (Ziehl's solution). Culture specimens of the organisms are also stained by the same reagent.

THE TREATMENT OF INFLUENZA IN ADULTS.

By REYNOLD WEBB WILCOX, M.D., LL.D.,

OF NEW YORK;

PROFESSOR OF MEDICINE AND THERAPEUTICS IN THE POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN TO ST. MARK'S HOSPITAL.

SINCE it is universally admitted that epidemic influenza is an infectious disease the theoretical treatment should consist in remedies which would neutralize or antidote the infection; but inasmuch as the infectious process is primarily of short duration and one attack does not render the patient immune against another, it is not likely that any preventive vaccine will succeed in either protecting the patient against an attack or in mitigating the severity of the disease in a patient already affected. So long as we do not know of any specific agent which will abort an attack, or mitigate the severity of the infection, it is proper that we should consider the subject under different phases and for each type endeavor to formulate a treatment.

Generally speaking, epidemic influenza will manifest itself in one of three forms, *viz.*, (1) that in which the brunt of the attack is upon the respiratory system, (2) that in which it is upon the gastro-intestinal system, or (3) that in which it is upon the neuromuscular system. Respiratory affections are evidently the most frequent and at the same time of more lasting moment, therefore it is of these that we will first consider the treatment.

At the outset in discussing the treatment of the respiratory form of epidemic influenza, certain clinical facts in relation to the history of the disease must always be borne in mind. First, and of diagnostic importance, is the fact that the prostration and the fever and the systemic disturbance are out of all proportion to the extent or severity of the disease as determined by physical signs. Next, granted a moderate involvement of respiratory area or even a disease stationary so far as extent of tissue is involved, this is no guarantee as to the prognosis in an individual case. The logical deduction from this observation is that we are dealing with an infectious process in which prostration is marked, in which supporting treatment is from start to finish urgently needed, and, while it may be very tempting to yield to the delusions of our ancestors and catch hold of that bugbear of the last generation and attack the fever as a morbid entity and subdue it, as we can, by a dozen different methods, it is undeniedly true that, while the results may be a better-appearing temperature chart, we have certainly done our patient injury. The more we know about fever as a symptom, the less we are disturbed either by its height or by its duration. If temperature must, in the opinion of the physician, be lowered, it is more effectually done by the ice-water coil over the heart than by any other method. So, also, pain may appeal to the routine practitioner as something that is to be attacked with vigor and the hypodermatic syringe and the morphine tablet be urgently indicated, perhaps even demanded by the patient; but the interference with nutrition and the damming up of the excreta would certainly leave the patient in a worse condition than would the pain.

However, specifically, what shall we do for a patient suffering from uncomplicated epidemic influenza attacking the respiratory system? First, free and comfortable expectoration should be obtained by methods which do not disturb the heart. First and foremost ammonium carbonate in five-to-ten-grain doses, repeated as frequently as the situation may require, each dose to be given in two ounces of milk, will relieve unnecessary coughing, will remove a great deal of the chest oppression, will fortify the heart, and, so far as I know, has only one disadvantage, *viz.*, the liability to produce a disturbance in the stomach after five or six days. The irritation of throat and nose is best relieved by sprays of ten drops of eucalyptol or five or ten grains of menthol to the ounce of albolene or other suitable liquid hydrocarbon. It is needless to say that the patient should be housed, kept in a room of equable temperature, not too hot, and that his diet should be a fluid one and as nutritious as possible. If the ammonia is not well borne, strychnine, either as good-sized doses of tincture of nux vomica or strychnine itself as a sulphate or nitrate, should be administered. Here we get not only the action of strychnine on the heart muscle and respiratory center, but as well its action on the cord and the resulting improvement in nutrition. As for the use of alcohol, the previous habits of the patient and the urgency of the symptoms call for consideration. Generally the patient is better without it. The methods for relief of pain will be considered later.

When from physical signs we find that we are dealing with pneumonia, then the teaching which we have already followed so carefully during the past few years must guide us. The bleeding of the lesser into the greater circulation by the nitrites, preferably nitroglycerin, and increasing and frequently-repeated doses of strychnine, must be carried out until the patient is convalescent. But inasmuch as the danger is not so much from the mechanical side as from the infection, every opening for elimination must be seized upon and every indication for supporting treatment followed. The skin, the kidneys and the bowels must not be neglected. For a slowly-resolving pneumonia and for a tardy convalescence from bronchitis, no drug yields better results than creosote carbonate, thirty or forty drops given in sherry several times a day.

It will be readily noticed that this scheme does not include any of the depressant expectorants, any of the depressant coal-tar products, or any of the physical means, such as poultices and cold- and hot-water applications or baths and various other indirect methods of obtaining what we perhaps get more readily by what has been outlined. The keynote to the situation is supporting the patient and eliminating the morbid products.

In the gastro-intestinal form of epidemic in-

fluenza the pain, nausea and vomiting all call for relief. At the outset I presume nothing is better than a thorough evacuation of the bowels by calomel given in small doses frequently repeated. Next comes intestinal antisepsis which can be accomplished by the organic bismuth salts, naphtalate, iodophthalinate, or, possibly, the subgallate. High intestinal irrigations aid much in the elimination of the toxins, not only by the bowels but also by the kidneys. Frequently rectal alimentation is urgently demanded and must be carried out. Sometimes small amounts of zoolak, small amounts of a good beef-extract (by that I mean those containing the albumins) will be retained when taken by mouth.

In the neuro-muscular type of influenza, the bone-breaking pains call for treatment, and for all that quinine, here as in other forms, has been lauded, personally I have found that the results obtained hardly warrant our pushing it to the extent which the severe infection would seem to justify. Euquinine seems somewhat more efficient, although statements made that it does not cause tinnitus are incorrect, for if administered in sufficient amount the tinnitus is quite as severe as that caused by quinine sulphate, for instance. Although there is great temptation to relieve the headaches and the muscular pains by the coal-tar products of the anilin series, those which are sufficiently analgesic are also to a greater or less extent cardiac depressants and their unrestricted use is by no means advisible. In fact, it may even be dangerous. For instance, Hale White reports that seventeen deaths from the use of antipyrin occurred during one epidemic of influenza in the city of Vienna alone. However, it is possible to relieve a large part of the suffering in this form of influenza by a combination of coal-tar products and salicylic acid or some of its forms without incurring dangerous depression in the circulatory and respiratory apparatus. This may be accomplished, for instance, by alternating phenacetin or acetanilid, of which the depressing action upon the heart is neutralized by caffeine, with acetanilid and methyl salicylate, or salipyrin, a combination of salicylic acid and antipyrin, may be administered to the extent of relief of pain; but, in spite of the laudation with which this drug has been favored, I have seen depression produced by its use, and here caffeine should always be employed to counteract its influence. If the practitioner will guard his analgesic of the anilin series with caffeine and limit the dose to that required for the relief of pain and to a less amount than that which disturbs the heart, we may feel much more confidence in advising its use. Kryofin seems more decidedly analgesic and less depressant than most of this series.

There is a rather neglected remedy which very frequently, though not invariably, affords great relief from the headaches and backaches so common in influenza. I refer to gelsemium, which should be pushed until slight ptosis appears, when the limit of its physiological activity has been reached. The success, when obtained, is so brilliant that it is really worth the trial, although, so far as I know, no exact indications can be furnished for its use, nor can *a priori* success or failure be predicted. Sometimes the muscular pains, if limited to the back, can be markedly relieved by external applications. For this purpose the best is a mixture of equal parts of kaolin and glycerin to which ten per cent. of boric acid has been added and a sufficient quantity of any volatile oil to make an agreeable odor, applied as a cataplasm in sufficient thickness and kept hot. This is cleanly, retains its heat and is renewed without difficulty.

I have already said that elimination of the toxins should be safeguarded. Fortunately constipation is not a common symptom in influenza. For the diarrhea which occurs in most victims no treatment is indicated. From the beginning a neutralization of the infectious material in the intestines should be brought about as already shown. The diarrhea should be looked upon as beneficial. Warm baths relieve muscular pains and, when accompanied by friction, keep the skin in good condition and add much to the comfort of the patient. Not only the presence of albumin and casts in the urine should be determined, but the specific gravity, the urea excretion, and, above all, the amount of urine passed should be carefully noted. For urinary insufficiency no better remedy can be found than continuous enteroclysis with decinormal saline solution at a temperature of 110° F., which not only aids renal elimination but is a cardiac stimulant of no mean importance.

This brief outline gives only the salient points which should be considered in the treatment of adults suffering from epidemic influenza. The important matters to be avoided seem to be (1) opium and (2) all measures which depress the circulation. Furthermore we should feel that, although we are dealing with an infection which is severe for a time, it is soon past and should, when carefully treated, leave no traces when it occurs in a healthy individual. It is epidemic influenza in old alcoholics, in diabetics, in persons suffering from arterial, cardiac or renal degeneration, and in old age, that our anxieties are awakened; but with avoidance of all depressing measures and a consideration not of symptoms but of the general aspect of the patient, *the treatment of the disease and of the patient,* success follows in a very large percentage of our cases.

A NOTE CONCERNING THE TREATMENT OF INFLUENZA BY THE EMPLOYMENT OF HYDROPATHY.

By E. L. SHURLY, M.D.,
OF DETROIT, MICHIGAN.

A DISEASE so common during the autumn, winter and spring seasons as influenza, and one presenting such different degrees of severity and complications cannot fail to enlist at all times the lively interest of the medical practitioner. Its symptomatology is usually typical in the first

stage or onset, although its course is irregular. Consequently its therapy calls for the exercise of good judgment in the selection of remedial agents. As before mentioned the first stage or onset is generally quite typical exhibiting a vasomotor disturbance represented by cephalalgia, coryza, faucitis and bronchitis. But soon after this other mucous membranes, one or more of the viscera, or the nervous system, may so participate as to change materially the phase of the case.

Whether the infection be at first local, and then general, is a question which need not detain us now. Suffice it to say that a disturbance of the upper respiratory mucous membrane of a neurotic and inflammatory nature is usually presented, and, from a therapeutic standpoint, whether it is due to the direct irritation of the morbific agent or whether this phenomenon is a salutory reaction on the part of Nature designed for the elimination or limitation of the infection is a question that ought not to deter us from prompt action, because it is obvious that an apparatus like the respiratory apparatus is in danger of serious injury, whether it be the seat of primary infection or whether it be the part selected for the elimination of the poison or its products in this disease. Moreover, we must recollect that the intensity of the first stage may determine serious inflammation and suppuration of the accessory cavities of the nose and of the ears as well as of the pulmonary apparatus itself, while the second stage may be characterized by serious neuropathies or visceral disease which may either prove speedily fatal or leave some distressing or incurable chronic ailment. Therefore even mild cases of influenza should not be left wholly to Nature for relief.

The first therapeutic indication should be to assist Nature in the elimination of the infection and in the modification of the action on the ganglionic nervous system. The accompaniment of this desideratum without endangering the life of the patient is not always easy—especially when the attack is tolerably severe; nevertheless a judicious conservatism should always be maintained. The well-known physiological sympathy between the mucous membranes and skin may in this instance he profitably brought into action by persistently stimulating the function of the latter apparatus. On account of the tendency to asthenia this cannot always be safely done by the employment of the so-called cardiac depressants or such diaphoretics as pilocarpin, antimony, etc., but it may be safely accomplished in nearly all cases by the persistent use of the hot-water bath, steam bath, or hot pack, in conjunction with quinine and mild anodynes. These should be used during the first stage quite freely, the patient may, however, receive a moderate dose of hydrargyri chloridum mite with sodium bicarbonate in the beginning, to be followed by a saline draught. He should he confined in a warm room as long as necessary and treated with hot-water baths, steam baths, or hot packs about once in two, three or four hours until free diaphoresis is established. This condition may be maintained by frequently administering hot bland or acid drinks.

When not contraindicated by some unusual condition of either the cardiac apparatus or central nervous system, the patient may be treated preferably by a series of steam baths which may be easily given by wrapping him in a blanket around and up to the neck and seating him upon a cane-seated or other chair with perforated bottom under which a vessel containing at least a gallon of very hot water is placed, then so arranging the blankets that the steam emanating from the vessel may rise and fill the space between his body and the blankets. This position may be maintained by the patient for a period varying from three to six minutes or until perspiration starts or the patient complains of faintness, when he is to be placed in bed (previously warmed) and wrapped in the same blankets that enclosed him while on the chair. This having been done moderately warm drinks may be administered, if desirable, to quench thirst and still further favor diaphoresis. If a hot-air bath is preferred, an alcohol lamp instead of the vessel of hot water is to be placed under the chair. When for any reason it is deemed inadvisable for the patient to sit up in the foregoing manner, the hot pack may be substituted. This manipulation is accomplished by placing under the bed-covering a number of hot bottles (rubber or glass bottles filled with very hot water) or hot flatirons, or bricks. These may be frequently changed until free perspiration is brought about. The practice of turning steam from a tea-kettle or other vessel directly under the bedclothes should be avoided because of the danger of irritating the skin of the patient by the too direct contact of steam. Another objection to this method, that of wetting of the bedclothes, is not an important one, inasmuch as a little dry rubbing with a towel or the subsequent placing of a few hot water bottles in the bed will readily prevent the chilling of the patient. Hot-water packs applied to various parts of the body are very useful substitutes for the more thorough application of the steam or hot bath.

The employment of the cold pack should take precedence over hot baths, etc., whenever the temperature is very high, for in such cases the leading therapeutic indication is to reduce the temperature from a dangerous to a safe degree, and then follow with hypodermic injections of normal saline solution, one ounce every hour until diuresis or diaphoresis has become established. By these measures the skin may be made to greatly assist in eliminating the poison, and also serve an important part toward preventing dangerous visceral congestions. Of course, if the physician is called in at a late stage of the disease, these measures will be inadvisable. Supposing, however, that the case has been seen early and these proceedings have been adopted with good effect, then quinine in three-grain doses should be given every two hours alone or

with opium or paregoric until the physiological effects are manifested. Especially to allay pain and distress should tinctura opii camphorata or opium be administered in good doses until the cough or other irritation abates, and expectoration has become established. This drug will be found safe and far preferable to any other as an anodyne.

Such a plan of treatment will not only modify the first stage of the disease, but will often cut short its course and prevent the subsequent events constituting the second stage, such as ethmoiditis, visceral inflammations, bronchitis, catarrhal pneumonia, etc. For the relief of debility and nervous perturbation, following the first stage, the administration of phosphorus (gr. 1/100) in capsule, in oil, will be signally effective toward giving tone to the system and assisting in the recovery of the normal metabolism. Strychnine, also, is highly useful in this connection as a general nerve tonic. Complications and sequelæ which may arise must be treated, of course, according to the circumstances of the case.

Although there are cases of asthenic character which admit of the use of the coal-tar products, their employment generally will be found inadmissible in the treatment of influenza.

32 Adams Avenue, West.

CLINICAL MEMORANDUM.

INFANTILE GRIP WITH UNUSUAL TEMPERATURE RANGE.

By L. E. LA FÉTRA, M.D.,
OF NEW YORK.

During infancy temperatures above 105° F. are not at all unusual; but rectal temperatures below 97° F. are rarely noted in the course of febrile disease. Slight ailments may readily produce high temperatures in the young, but subnormal temperatures seem to indicate a profound disturbance of the child's metabolism, and are produced by severe infections, such as grip, malaria and pyemia. The case reported presents an unusual combination of very high and very low temperatures, along with some other noteworthy features.

The patient, a fine girl baby thirteen and a half months old and weighing twenty-three and a half pounds, had been perfectly well until February 27, 1899. That morning she had a sudden rise of temperature to 103° F., without vomiting or convulsions: when seen in the afternoon there was rapid, labored breathing and a temperature of 103.8° F. It was evident that she had a pneumonia, although the signs were not clear; but the next day there was plainly a consolidation of the right upper lobe. No other lobe became involved, and the disease pursued a typical course for pure lobar pneumonia in infancy, the defervescence occurring by lysis, as shown in Chart I., and the lung clearing up completely in less than two weeks. The only treatment was the application every three hours for twenty minutes of cold compresses wrung out of salt water at 70° F. The baby stood the attack well, losing only half a pound during the two weeks. On March 11th she was playful, had a good appetite, wanted to get out of bed, and seemed thoroughly convalescent.

But early on the morning of March 13th, without any apparent cause, the baby seemed profoundly prostrated, with her skin cold and "all goose-flesh," and the temperature was found to be only 97° F. Later that day it was 99.4° F., and then it began the startling and erratic course shown in Chart II. On March 14th 103.8° F. was the highest record, and it seemed probable that the lung was being attacked a second time by the pneumococcus. The next afternoon, however, the record stood at 97.6° F., but by midnight it was at 106° F., and the same high range was reached again on March 16th at 6 P. M. In the twenty-one hours following there was a fall of *nine degrees* to 97° F. In the next thirty-six hours there was an excursion up to 105.2° F. and down again to 94.6°, the last being a drop of *ten and a half degrees in twenty-one hours*. For the next three days the fever remained fairly high, but at 1 A. M. on March 22d the lowest observation was made, a temperature of 94.4° F.

The treatment had been merely symptomatic and supporting, so that the falls in the temperature were not to be ascribed to antipyretic drugs. Along with the peculiar temperature, there were great prostration, almost complete anorexia, and a mumbling delirium when the temperature was high. The emaciation was rapid, due jointly to the high temperature and the refusal of food, the loss in weight averaging over three-quarters of a pound per day. There was no pain nor tenderness, no cough nor any catarrhal discharge from the eyes, nose or bowels.

The case was a puzzling one, for in the wake of pneumonia such violent excursions of temperature suggested empyema or some other pus process, such as pyelitis or pyemia. The physical signs in the abdomen, chest and throat were negative, and there was no tenderness around the ears. The urine showed no pus-cells nor any reaction for peptones. Other possibilities then left were malaria and grip. Careful and repeated examinations of the blood for malarial organisms proved negative, and, as already stated, there was no enlargement of the spleen. The diagnosis of grip, therefore, was made by exclusion. It is regretted that no search was made for the Pfeiffer bacillus, even though this germ is not always found in all cases of a grip epidemic. The correctness of the diagnosis was confirmed, however, by the subsequent history.

On March 22d Dr. Holt saw the case with me in consultation, and advised immediate removal to some country place where there were no cases of grip. Lakewood was at that time such a place, and accordingly the baby was taken there on March 24th. A rapid change in the type of

the fever was evident. At no time after the change of air did the temperature rise above 99.2° F, nor fall below 96.4° F. After the sixth day in the country the temperature was practically normal. From the time of arrival improvement in the general condition began, and the child increased rapidly in weight so that at

moval from the house was followed by rapid return to health, and there has been no third attack. As a result of this experience with sulphur fumigation, I now insist that formaldehyde be used thoroughly to disinfect every room in which a case of grip has occurred, and thus far I have had no reinfections.

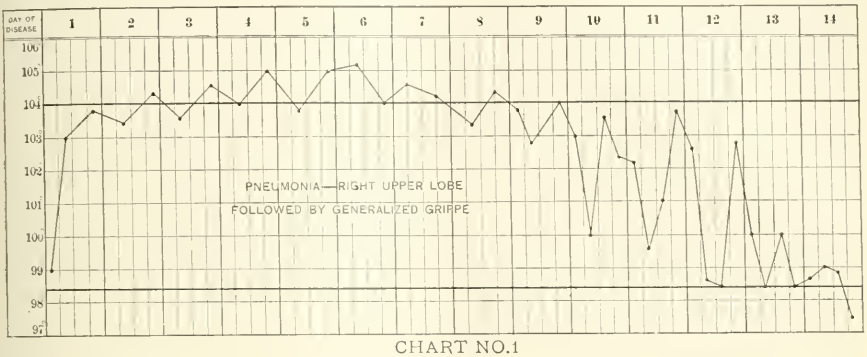

CHART NO.1

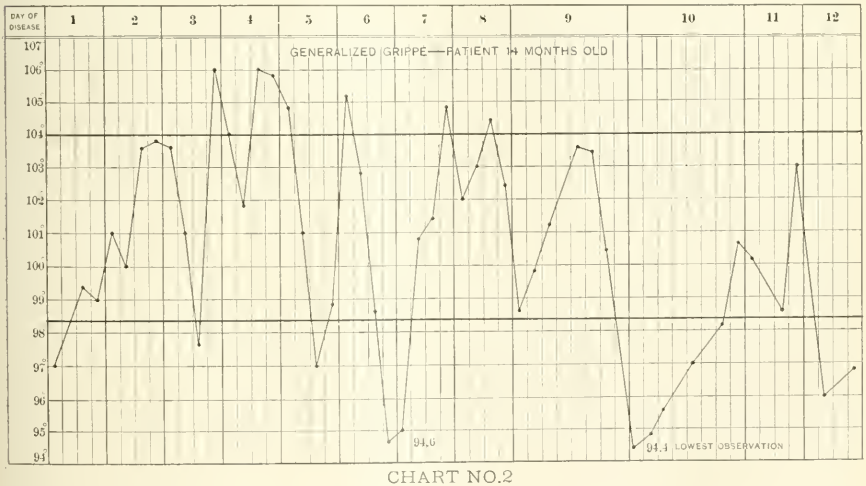

CHART NO.2

the end of four weeks she had almost entirely regained the nine pounds lost during her eleven days' illness.

While the family was in the country the house was fumigated with sulphur and thoroughly aired, so that in the fall when the family returned it was thought safe for the baby to be put in the same nursery. In less than two weeks she had a second attack of the grip, but this time the course of the disease was milder, the temperature ranging only from 98° to 105° F. Permanent re-

The particular features of interest in the case are as follows:

1. The very low temperature, 94.4° F., showing profound infection.

2. The wide excursions of temperature, a fall of ten and a half degrees being noted in one instance.

3. The efficacy of change of air as the sole curative treatment.

4. Retention of the grip germ in the house for several months, in spite of sulphur fumigation.

MEDICAL PROGRESS.

Value of Oliver's Symptom.—Downward or lateral pulsation of the larynx has been frequently described as a symptom pathognomonic of aortic aneurisms. F. Jessen (*Münch. med. Woch.*, Nov. 6, 1900), however, cites a case in which the sign was distinctly present and where the autopsy disclosed a large round-cell sarcoma of the mediastinum which strongly compressed the arch of the aorta against the trachea and esophagus. Conversely, the diagnosis mediastinal growth had been made in a second case in which after death an aortic aneurism was found which was closely adherent to the trachea. Oliver's sign thus gives but little help in the differential diagnosis between both disorders.

Purulent Synovitis of the Large Joints.—The importance of the time and methods of treating this condition are thus summarized by O. Hartmann (*Deut. Zeitschr. f. Chir.*, Bd. 57, Hft. 3 and 4). In the earliest stages of inflammation of the knee-joint the custom at the clinic in Jena is simple aspiration, the most thorough possible evacuation and the injection of five-per-cent. carbolic acid solution. When the condition is more advanced trochar and cannula are used to empty the joint of pus and rubber drain tubes are inserted through the large punctures. In more severe infections the joint is opened as in the Volkmann resection, omitting division of the quadriceps tendon. Thus very thorough drainage is obtained. If this fails, by simply sawing through the patella a full resection is possible at ease. Abscess of the calf is handled successfully by cutting out the head of the fibula and drainage posteriorly. If to the abscess deep burrowing of the pus and tibial osteomyelitis are added, amputation is indicated. These openings into the joint may be followed by partial or complete failure of function. In one case with an unhealed wound the patient showed 25 per cent. of full function. By improper after-treatment this advantage was lost. It is precisely the after treatment that is all important. When the ankle is moderately involved, curved axial incisions behind each malleolus will aid. In worse cases the incisions of König added each side of the extensores permit through and through drainage. When such interference has failed and pus is spreading, before thinking of a low leg amputation, a resection through these incisions may be done or after the manner of Langenbeck and Hüter. In the adult the hip always needs resection. In children, when the pus has not burrowed through the adductores, the head of the femur is carefully cleaned and the acetabulum and capsule drained posteriorly. The wrist offers best prognosis under resection. Pus in the elbow and shoulder have occurred at this clinic so rarely that the author can offer no well-proved procedure for treatment, since several have been tried and none yet selected for its great success.

Hand Disinfection.—F. Schenk and G. Zanfal (*Münch. med. Woch.*, Nov. 6, 1900) come to the following conclusions with regard to the best methods for disinfecting the hands: (1) The mechanical cleansing is done more efficiently with sand soap than with soft soap and brush. (2) This is also true for the field of operation. (3) The mechanical cleansing should last five minutes, to be followed by washing for three minutes in one of the following solutions: Sublimate, 1-1000; mercury oxycyanide, 2-1000; or ethylendiamine mercury citrate, 1-1000. In all cases the solutions should be hot.

Colostomy.—In the interests of simplicity and brevity H. Hartmann (*Revue de Chir.*, Nov., 1900) has brought out the following technic which is claimed to avoid prolapse of the artificial rectum and anus, cicatricial contracture of the orifice, protrusion of hernias, absolute incontinence, and escape of feces into the lower loop, all or any one, so common in the ordinary artificial anus. Through a ten-centimeter incision, two centimeters within the anterior superior iliac spine, centered upon and perpendicular to a line joining the spine and the umbilicus, the abdomen is opened in the intramuscular method of McBurney. A loop of the descending and sigmoid colon is drawn far out of the wound, the lower loop being as short as possible and the upper limb redundant. When the mesentery is defective, one is created by stripping off parietal peritoneum from the fossa and suturing it over the gut posteriorily. The mesentery, normal or artificial, is then transfixed by a large strip of iodoform gauze and the same material is packed about the bowel between it and the lips of the wound. No sutures whatever are used, and ordinary sterile gauze dressing is applied. After twenty-four or forty-eight hours a small opening is burned through the longitudinal band (which should always be arranged so as to traverse centrally, anteriorly and from above downward over the loop), opposite the upper segment of the protruding bowel near its emergence. On the sixth or seventh day the packing about the loop is taken off and on the tenth day the supporting gauze is removed, first by drawing it upward and then cutting it across close to the mesentery, thus the large, matted extremities, often soiled with feces, are not pulled through the depths of the wound. The function of this anus is almost always excellent and recovery from the operation simple.

Fibroids in Non-Pregnant Uterus.—After discussing the different methods of treatment of this condition, E. F. Fish (*Am. Jour. Obstetrics*, Nov., 1900) says that, from personal observation, *myomectomy* is the operation of choice (1) when the tumor is pedunculated; (2) when it is single, whether subserous, interstitial, or submucous, and can be enucleated without loss of

uterine tissue, and the tumor cavity can be closed and covered with peritoneum; (3) when the desire for an heir outweighs all other considerations. That *hysterectomy* is indicated (1) when the tumor involves so much of the uterus that a cavity too large to be properly closed and covered with peritoneum would follow its removal; (2) when several tumors exist, especially little nodules; (3) when the adnexa are diseased to such an extent that they must be sacrificed; (4) when the disease ceases to be local; (5) when hemorrhage, pressure, or great pain is a persistent symptom; (6) whenever malignancy is suspected or the tumor is of rapid growth; (7) after change of life. That *palliative treatment* is indicated (1) when the patient is very much reduced from loss of blood, as a prelude to radical cure; (2) when the existence of chronic nephritis, diabetes, tuberculosis, or other constitutional disease forbids radical cure; (3) when the patient is past forty years of age, the tumor small, the main annoyance hemorrhage, and she is desirous of awaiting the effect of the menopause.

Treatment of Typhoid.—The treatment of typhoid fever at New York Hospital is detailed by F. C. Keays (*Med. Rec.*, Dec. 1, 1900). The routine treatment consists regularly of the use of the tub-bath given every three hours when the temperature is 103° F. or over. The bath is usually started about 80° F. and run down to 70° F. or 65° F. for a period of ten to fifteen minutes. When tub-baths are not taken well, alcohol sponge-baths are used, the alcohol being cooled by ice. When there is a contraindication to baths, acetanilid, grs. iij, may be used every three hours. For sleeplessness combinations of trional, grs. xv, with codeine, gr. j, work well. The baths generally prevent delirium. Whisky is efficacious, especially in alcoholic patients. Hypnotics are frequently given by rectum in very delirious patients. Nausea and vomiting are relieved by milk modified with cerium oxalate, grs. v, and sodium bicarbonate, grs. x, to milk, ℥ viij. Distention is treated by turpentine stupes, rectal tube and turpentine by mouth, ♏ v-x, or enemata. Whisky and digitalis are used as heart stimulants as indicated. If hemorrhage appears, the patient is kept quiet, cold is applied to abdomen, saline enemata given to replace the blood lost or saline infusions are used. Milk forms the diet during the course of the disease, but kumyss, broths and beef-juice are frequently given. As soon as the temperature reaches normal the diet is rapidly increased. As little medication as possible is given during the course and convalescence.

Gonorrheal Rheumatism.—In an interesting account, based upon an analysis of 250 cases of gonorrheal rheumatism, G. Lorimer (*Quarterly Med. Jour.*, Nov., 1900) finds that the ages ranged from 17 to 58 and that by far the largest number of patients were males. This he explains is more due to difficulties present in recognizing the disease or the chronic discharge in females. The time from the onset of the gonorrhea to the occurrence of the arthritis averages three months in women and six weeks in men. A hereditary tendency to rheumatism was observed in so few cases as to be merely coincidental. Pyrexia was generally present, usually of subacute type, though acute and chronic cases were not infrequent. In two instances, the pyrexia was distinctly hectic in type. The absence of a tendency in the arthritis to shift from joint to joint was a characteristic feature except in those cases in which the initial fever was acute. The degree of pyrexia was observed to regulate the amount of perspiration and the concentration of the urine and the peculiar acid odor of the perspiration of acute rheumatism was always absent. The absence of hyperinosis and oligocythemia was a fairly destructive feature, but seemed to depend more on the degree of fever. Cardiac complications were rarely present. There was no evidence to show that previous attacks of rheumatism had any influence in increasing the liability to gonorrheal arthritis except in the acute type. The order of frequency of involvement of joints was as follows: Knees, ankles, hands and wrists, hips, shoulders, temporomaxillary joints, cervical joints and sternoclavicular joints. Other complicating affections were non-purulent conjunctivitis, sclerotitis and iritis, neuralgia of the lumbar plexus and of the sciatic nerve, myalgia and painful affections of the fasciæ, especially the plantar. There was generally noticed a much greater liability to chronic articular changes than in ordinary rheumatism. Muscular atrophy, usually proceeding *pari passu* with the arthritis, was occasionally observed. Salicylates only proved of value in those cases in which the onset was acute, in which case their efficacy disappeared with the advent of subacute symptoms. In conclusion the author asserts that the explanation of gonorrheal rheumatism is still *sub judice*, but he inclines toward the toxemic theory.

Hereditary Aspect of Pernicious Anemia.—Many of the diseases of the human organism are now supposed to result from an inherited feeble resistance to certain deleterious agents. In muscular dystrophies the muscular system is congenitally short-lived. In hereditary chorea and certain forms of dementia the central nervous system begins to degenerate while the remainder of the body may be in excellent condition and the patient be in the prime of life. C. L. Dana (*Med. Rec.*, Dec. 1, 1900) reports a case of pernicious anemia in which the family history is very suggestive of a possible teratological defect or weakness in the blood-making organs. The patient, aged forty-seven years, was the thirteenth of fourteen children, all of whom were born dead except one brother next in age to himself, who died from pneumonia. Both father and mother were healthy, but the patient was born when the

mother was about forty years old. No history of syphilis could be obtained, and this trouble rarely causes more than three or four miscarriages. The history of the family shows an extraordinary lack of vitality on the part of the generation to which the patient belonged, and, as frequently happens in a long series of still-born children, those who finally survive have teratological defects, it is believed that this congenital weakness was expressed in the patient reported by the early degeneration of his blood-producing tissues.

Yohimbin, a New Aphrodisiac.—Yohimbin, the alkaloid of the bark of a tree endemic in West Africa, has been found by L. Löwy (*Therap. Monatshft.*, Nov., 1900) to produce marked congestion of the sexual organs and possibly also new formation of spermatozoa, without, however, irritating the kidneys as is the case with cantharides. In the impotence of tabes and other organic diseases no influence on sexual function could be detected; on the other hand, irritable weakness or paralytic impotence was favorably affected. The proper dose is 5-10 minims of a one-per-cent. solution of the hydrochlorate three times daily.

Retroperitoneal Fibromata of the Uterus.—After considerable experience the following results of surgical attack upon these tumors are presented by D. de Ott (*La Gynécol.*, Oct. 15, 1900). He handled his cases either by the abdominal or the vaginal route. In the former cases after free exposure of the deep field, the peritoneum was divided longitudinally and stripped in two broad flaps off the tumor. The mass was then enucleated or excised clean and the cavity packed carefully with gauze, the end of which emerged through the vaginal vault. The abdominal wound was closed by tier sutures and the vagina was lightly packed with gauze. Of 189 examples of this procedure 20 were fatal (10.6 per cent.). In his later series the vaginal route in front or back of the cervix uteri was always used. Generally the enucleation could be done *en masse* and extraperitoneally; occasionally it had to be done *en morcellement* and the serosa divided. The rest of the technic was the same as the previous manner. By the vagina he has also removed submucous fibroids by dividing the posterior wall of the body into its cavity enucleating and then suturing. Of 193 cases only 6 died (3.1 per cent.). His conclusion is that the vaginal approach should always be considered before resorting to laparotomy.

Gastroptosis.—The condition of gastroptosis depends so much for its symptoms upon the accompanying lesions of the stomach, such as atony, gastritis, and disorders of sensation and secretion, that no clear picture of the condition has yet been painted. G. R. Lockwood (*Med. Rec.*, Dec. 1, 1900) reviews forty-five cases that he has had under observation in private practice and urges that it is not the position or size of the stomach which causes the disturbance, but the ability of the organ to digest and pass the food on into the intestine. In ten cases without atony there were practically no symptoms, but in those cases in which atony became more marked the symptoms were so constant and severe that the patients were incapacitated for work. He believes that the displacement of the stomach is a predisposing cause of a variety of gastric neuroses which are usually induced by definite mental or physical strain and points out that all his cases of marked atony were decidedly neurasthenic. The gastric acidity is increased in direct proportion to the atony unless counteracted by gastritis which, by reducing the acidity, often lessens the severity of the symptoms. In a large number of cases inattention to the conditions of atony, of neurosis and of gastric secretions has led to an unsuitable, insufficient diet which reacts upon the general condition and the disturbances within the stomach. The amount of gastric distress does not depend upon the quantity or quality of the food and if the irritation be allayed the more they eat the better. A combination of bromide, grs. vj-viij, chloral, grs. iij, resorcin, grs. iij, and chloroform-water, dram j, with gtts. vj of spirits of anise, ounces iv, to disguise the taste, has seemed the most serviceable. The Neptune girdle is a most efficient means of soothing gastric irritability. Two layers of flannel, large enough to cover the entire abdomen, are wrung out of hot water as dry as possible and covered with oiled silk. They are changed twice a day and worn constantly. Mental and physical rest is frequently needed. To reduce the hyperacidity frequent feedings of mixed foods and alkalies after meals are used, such as magnesia, magnesium carbonate, or bismuth.

Actinomycosis Hominis.—The following clinical data are given by J. C. Oliver (*Annals of Surgery*, Oct., 1900) of a case of actinomycosis of the head and neck. Jeweler, forty-nine years old; carcinoma in immediate family; no syphilis; six years ago while suffering from purulent discharge about the teeth a papillomatous, ulcerating, non-indurated patch developed just inside the vermilion border of the left angle of the mouth, with a few metastases, all healing after scraping and leaving a white scar. All the lower teeth were extracted for the pyorrhea except the last molars, which served as anchors for the false teeth-plate. In June, 1899, an ulcer developed opposite one of the clamps in the cheek, spreading after the exciting cause was removed, curetted July 2d following with some improvement. The scrapings were negative as to carcinoma and tuberculosis and hence syphilis was diagnosed in consultation. Iodism was at once induced and maintained, without local relief. Pain now appeared and the ulcer extended to the lips. Late in September enlargements beneath the maxilla appeared. October 7th deep but futile scraping of the ulcer. Epithelioma was now

diagnosed, in the presence of hard masses in the neck, about the body and angle of the lower jaw. Radical operation was now declined. A little later the masses softened and then fluctuated, were incised and evacuated of suspicious actinomycotic pus, but microscopically negative. January 4, 1900, radical ablation was done, but the growth appeared in the incisions, sinuses resulted and discharge of the thin green-yellow curdy pus. Edema of the adnexa began and the nose and throat, with dysphagia, were involved. Finally in the discharge of one abscess the streptothrix and ray fungi after prolonged search were found. Potassium iodide was now pushed, but without promising results. Death occurred March 3, 1900, after a copious hemorrhage, which was stopped by packing, but overtaxed the patient's strength.

Pulmonary Emphysema and Nasal Occlusion.—Dr. Cousteau (*Journal of Laryngology,* Nov., 1900) gives results of experiments on rabbits. One nostril was obliterated and rabbits killed seven months after. Lungs were emphysematous, here and there transparent vesicles, size of a pin's head, appearing in white raised plaques. Under microscope alveolar walls were seen thinned and even burst in places. Similar result was obtained in twelve days by obliterating both nostrils in a rabbit. The importance of maintaining permeability of the nose depends on the rapidity with which even incomplete stenosis of the nose could give rise to pulmonary emphysema.

Tonsils and Adenoids.—From 1892 to 1900 Cuvellier (*Jour. of Laryngology,* Nov., 1900) treated 2785 children at the Hôpital des Enfants Malades. Of these 569 were simple tonsillar hypertrophy, 1060 simple adenoids, and 1156 tonsillar hypertrophy with adenoids. Medium age five to seven years. Adenoids greatly preponderating. Tonsils removed by tonsillotomy when pedunculate, piece by piece when flat or lacunar, did not recur. Adenoids were found in (1) respiratory, (2) auricular and (3) mixed types—2019 cases giving 1214 of respiratory, 75 auricular and 730 mixed. Operation was obligatory for removal. Complications were rare. There were no contraindications except hemophilia. Radically removed, no recurrence.

Bacteriological Diagnosis of Diphtheria.—"Not every membranous sore throat, or laryngitis, is due to infection by the Klebs-Löffler bacillus" and "many mild and non-membranous sore throats do depend upon infection by this organism. It is the presence or absence of the specific bacillus which is now held to decide whether or not a given case is to be regarded as one of diphtheria." So says Dr. Andrews, Pathologist of St. Bartholomew's Hospital (*Jour. Laryngolog.,* Nov., 1900). The diphtheria bacillus has tendency toward "clubbed" form, stains irregularly, owing to metachromatic granules in their protoplasm, has no spore-formation, has no flagella, is non-motile, stains by Gram's method, and does not liquefy gelatin. The size and form of the bacillus admits of variation and the non-pathogenic bacilli may resemble exactly the pathogenic and are not to be distinguished thus, for example, the xerosis bacillus. The acid-producing character of the pathogenic form is confirmatory, but not reliable. The death of an inoculated guinea-pig with the characteristic symptoms is a valuable diagnostic aid, but not absolute. Absolute criteria of pathogenicity may be unattainable. Given requisite time for experiment the pathologist can recognize pathogenic diphtheria bacilli, "but ultimate diagnosis must always rest with the physician who knows all about the case." "Virulent bacilli may be present in the throats of healthy persons who have been in contact with unhealthy persons." . . . "Bacilli like diphtheria may be present in the healthy nose." The bacteriologist should always be given clinical details with material furnished him. "It has happened to me to fail in demonstrating the bacilli during the life in a case of undoubted clinical diphtheria." Negative results are much less conclusive than positive ones.

Retroflexion of the Uterus.—E. Schroeder (*Zeitschrift f. Geburtshülfe und Gynäkol.,* B. 43, H. 3) in view of the frequency of this condition without symptoms publishes the following instructive statistics: First, 90 nulliparæ with 23 retroversions and 7 retroflexions. Of these, the first group, 74, had no pains in the lower segment of the body, although 19 had retroversion and 5 retroflexion; 25 were virgins of whom 8 had version and 2 flexion; the other 49 were married or had had intercourse, 11 showing the backward version and 3 flexion. The second group with symptoms, chiefly pain in the lower part of the trunk, comprised 16 patients with 4 suffering from version and 2 from flexion; among them 3 were virgins with 1 retroflexion uteri and 13 were not virgins, 4 presenting version and 1 flexion. Second, he investigated parous women previous to menopause with these statistics, in all 276 cases, 40 versions and 31 flexions. The group without symptoms was again the larger, 191 with 25 versions and 17 flexions. The series having trouble comprised 89 women, 15 with version, 14 with flexion. His last class included all women past menopause, 45 total, 13 versions, 4 flexions, namely, 38 with no pain, among these 9 versions and 4 flexions, and 7 with pain in 4 individuals with retroversio uteri.

Phlegmasia Alba Dolens.—After a thorough trial of wet dressings of lead and opium and aluminum acetate upon a well-marked case of this condition, A. Herzfield (*N. Y. Med. Jour.,* Dec. 1, 1900) employed Unguentum Credé, fifteen grams, rubbed into the affected extremity daily for two weeks, and found that it had a most beneficial effect which was noticed almost immediately after this method of treatment was begun.

THERAPEUTIC HINTS.

Purulent Pericarditis.—This is a not uncommon accompaniment of prolonged productive pneumonias, according to Bard and Machard, and should be continually watched for. The diagnosis being proven by exploratory puncture, a transverse incision, 8 to 10 cm. (3 to 4 in.) long, is made over the fifth left costal cartilage, beginning a finger's breadth from the sternum. The cartilage is removed, the internal mammary cut between two ligatures, and the pericardium opened and evacuated. After thorough lavage a drain is left in the lower angle and the wound sutured.—*Revue médicale de la Suisse Romande.*

Asthma.—Of palliative remedies, writes W. H. Thomson, the first place belongs to the group containing belladonna, hyoscyamus, stramonium, and duboisin. Hot coffee, very strong, taken on an empty stomach and sipped, acts as a stimulant nervine. Taken after eating it aggravates the asthma by interfering with digestion. Next in value are alcohol, the ethers, chloral, and opium. The fumes of potassium nitrate are very effective. But these remedies do not cure, and it must be remembered that asthma is at no time absent from the asthmatic. In hay asthma the inhalation of carbolized steam or turpentine vapor, twice a day for months, may produce a permanent change in the sensitive mucous membrane. A dose of potassium bromide, grams 2.0 (gr. xxx), with Hoffmann's anodyne, grams 4.0 (ʒ j), at bedtime, will often ward off an attack. Many cases of bronchitic asthma are relieved by wearing light under-flannel, which prevents the condensation of perspiration and susceptibility to draughts. Peptic asthma is especially influenced by the state of the alimentary canal. The best meal should be taken early in the day and only the lightest supper allowed at night. Bismuth with powdered calumba or sodium benzoate will often prevent an attack. Of remedies with lasting and curative power arsenic and potassium iodide are by far the best, and they should be combined with nervines and correctives. Of the latter, quinine and cod-liver oil are best with arsenic, and phosphorus and tincture of iron with iodide. A good prescription is:

℞ Potass. iodid..... 6.0 (ʒ iss)
Liq. pot. arsen..... 4.0 (ʒ j)
Spt. aether. comp.....75.0 (ʒ iiss)
Tinct. bellad..... 8.0 (ʒ ij)
Syr. aurant. cort....ad 180.0 (ʒ vj)
M. et sig.: Two teaspoonfuls in water an hour after meals.—*Reference Handbook of the Medical Sciences.*

Secondary Anemia.—According to R. C. Cabot, many cases recover with no treatment but the removal of the cause to which the anemia is secondary; as a rule, however, recovery is considerably hastened by therapeutic measures. There is no especial appropriate diet, but what is needed is a full and varied nutrition, which includes plenty of red meat. The digestion may need attention, and not infrequently there is gastric hypersecretion. Diarrhea or constipation are treated symptomatically. Climatic change is of service, especially high altitudes, where the rapid increase in blood-corpuscles appears to be not entirely transitory. Blaud's pill is the best form of iron, two 0.3 gram (5 gr.) pills, three times a day, increased in a week or so to three pills. In the rare cases in which Blaud's are not well borne or do not increase the hemoglobin rapidly enough, one of the organic preparations, such as ferratin, should be tried. The tincture of the chloride of iron should rarely, if ever, be given, on account of its strong tendency to produce constipation, its deleterious effects upon the teeth, and its disagreeable taste. All preparations of iron should be given after meals. Occasionally arsenic is useful, especially in the severer grades of anemia. It is best given as Fowler's solution, two drops after meals; well diluted, increased one drop daily until the physiological limit is reached, as shown by the occurrence of itching or burning of the eyelids, nausea, or vomiting.—*The Reference Handbook of the Medical Sciences.*

Dewees' Emmenagogue Mixture.—This preparation H. C. Wood relies upon almost exclusively in the treatment of simple atonic amenorrhea. The amount of iron should be regulated according to the anemia; of the aloes, according to the bowels; of the cantharides, according to the susceptibility of the urinary organs. The formula is:

℞ Tinct. ferri chloridi..... 12.0 (ʒ iij)
Tinct. cantharidis..... 4.0 (ʒ j)
Tinct. aloes..... 15.0 (ʒ ss)
Tinct. guaiaci ammon.... 45.0 (ʒ iss)
Syrupi q. s.....ad. 180.0 (ʒ vj)
M. et sig.: Tablespoonful three times a day.—*Therapeutics, Its Principles and Practice.*

Treatment of Chorea by Arsenic and Bromides.—There is a tendency to-day to treat ordinary chorea by very large doses of arsenic. Bechterew does not believe in this practice. He thinks that excellent results can be obtained by giving the bromides at the same time with reasonable doses of arsenic. He prescribes Fowler's solution in ordinary doses, according to the age and tolerance of the little patient, and at the same time gives the following mixture:

℞ Adonis vernalis.... 2.50 (♏xxxviij)
Aqua .....180.0 (ʒviiiss)
Ft. Infusion.
Then add:
Bromide of potassium.
Bromide of sodium.aa 4.5 (grs. lxviij)
Antipyrin ..... 2.0 (grs. xxx)
Simple syrup .....16.0 (ʒiv)
M. Sig. A teaspoonful 3 or 4 times a day to a child of ten years. *La Presse médicale,* Sept. 22, 1900.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

CUI BONO?

One of the most pitiful phases that the practitioner meets in his daily work is the yearning of the sick man to seek after strange gods. The honest physician feels keenly the imputation of self-interest and of incredulity by his patients when he tells them frankly that he believes there is no virtue in a treatment that they are anxious to try; and he never feels more helpless than when he sets before an eager, frightened man some of the broad truths of science on which his treatment is founded, and is met by a recital of the guaranteed cures that have been quoted to him by the advocates of some "system." There is always a physician of a regular school of medicine to back the cure, years of success in foreign lands, untiring fortitude toward the intolerance of narrow-minded doctors, and a list of prominent men whose maladies have been cured after well-known physicians had given them up. To doubt at least a possible efficacy in the face of such overwhelming evidence is but to display that illiberal, jealous spirit of skepticism that the overbelieving too readily apply to the medical profession.

A case in hand will serve to illustrate our point. There has been much said recently about the electrical treatment for tuberculosis. Probably there is hardly a physician in New York who has not at some time cut down his income by sending a tuberculous patient away from his own care to a more favorable locality, and advising him to spend his substance on rest, climate and food, only to find in a short time that same patient back in the city at his old vocation, and putting all his faith and money into some well-advertised cure for consumption. Among all of these the treatment of tuberculosis by electricity has sounded the most plausible to the popular ear. That the germicidal effect of drugs could be made to permeate the lung tissue by cataphoresis was suggested to physicians also, as a new development along well-recognized lines, and the usual appeal for a fair trial on a scientific basis was not denied.

It is characteristic of scientific men, although they are not often credited with such liberality, that they are always willing to test any new idea that may have a shadow of reason in it. Even though they know that certain laws of Nature preclude certain results, yet living in the decade of Argon and the X-rays, they recognize honest, faithful experimentation as the only key to mystery.

With singularly generous motives St. Luke's Hospital of New York consented to experiment upon a method of treatment by electricity of which the claims were: "One hundred per cent. of cures in the incipient stages, 75 per cent. in a secondary stage and 50 per cent. of the cases that would under regular treatment be considered hopeless."

The treatment was given regularly and systematically. Not only were the bacteriological examinations and blood-counts made at the Hospital, but the sputum was sent to the New York City Board of Health, where experiments were made upon guinea-pigs with the supposedly attenuated virus to see whether there was any actual lessening of virulence of the tubercle bacillus.

These experiments were carried on carefully, exactly and hopefully for three months with *absolutely negative results.* None of the changes that were claimed would take place eventuated, from the bacteriological standpoint. The effect of placing the patient in front of the static machine was as ineffectual as placing him before a mirror. None of the patients of the experiment improved any more than did others of like degree of infection on the same good food, regular hours and rest. The unbiased, scientific opinion of all the physicians who assisted at the work at

St. Luke's was, "Nothing in it," as is evidenced by the following circular which is being sent out in answer to all inquiries on the subject: "Replying to your letter, I would say that Mons. Crotte's method of treating tuberculosis by electricity was on trial in this hospital for three months, under the supervision of the Medical Board. Several months ago the Medical Board declared the results to be negative, and asked permission from the Executive Committee to cease their investigations, and to have the apparatus removed from the Hospital. This has since been done."

And yet, as the story goes, the experiments at St. Luke's are being quoted by the advocates of the electrical treatment as conclusive evidence that the method is vouched for and practised by the most reputable hospital in the country. References to them have been made in medical meetings and medical literature, always with the assumption that the test experiments were successful. That such assumptions have been denied and the promulgators of them snubbed makes no difference to those who are sounding the clarion for the cure of tuberculosis by electricity. Their point has been gained.

The public does not hear the authoritative denial of competent physicians, and, if it does, it is easy to say, "Doctors disagree." Thus the suffering patient is imbued with new hope, which leads him to abandon the only possible chance he may have for his life for a course of well advertised treatment, and the physician who has carefully and conscientiously advised him, without considering his own pocket, has to see that hope die when it is too late to follow his advice. What wonder that he signs the death certificate with *Cui bono?* on his lips!

THE THERAPEUTIC VALUE OF PROTARGOL IN DISEASES OF THE EYE.

Since the discovery of protargol in 1897 by the chemist Eichengrün and its introduction as a therapeutic agent by Benario, much literature has accumulated concerning its value in the treatment of certain ocular diseases; and a recent review by Von Sicherer (*Zeitschrift für Augenheilkunde*, September, 1900) is of much interest in showing the remarkable difference of opinion that is entertained regarding it by many experienced and trustworthy observers.

The advantages claimed for protargol are its great germicidal action, its penetrating power, the limited degree of discomfort produced by the applications and the absence of any slough.

The affections of the eye in which the drug seems to have been most generally employed are acute and chronic conjunctivitis of the catarrhal type, purulent conjunctivitis, both gonorrheal and non-gonorrheal, acute and chronic trachoma, blepharitis, suppurative lesions of the cornea and suppurative diseases of the lachrymal duct.

The results obtained from its use have been widely different. Some authors reported cure of the diseases under treatment within a few days' time; others that the results were totally indifferent, and still others that the cases under observation became so much worse that the treatment was necessarily abandoned. Observers also differ much in regard to the strength of the drug to be employed, it having been used from ¼ per cent. (Pflüger) to the pure powder (Darier), though from 20- to 50-per-cent. solutions seem to be those in greatest favor. Those authors reporting the best results claim that a 20-per-cent. solution is about as weak as can be expected to give rise to any benefit and that in very severe cases it must be employed in solutions much stronger. In fact, it is urged by the advocates of protargol that one of the causes of failure among those who report unfavorably concerning its value is the weak solutions that were employed.

Regarding the inefficiency of the drug Lesshafft has directed attention to the fact that in preparing the solutions there frequently occurs, by an excessive heating, a splitting of the silver molecule, making the preparation less active. He states, therefore, that it is best to triturate the powder in a porcelain mortar with as many drops of glycerin as there are decigrams of protargol and then to add cold water drop by drop.

The manner of employing protargol varies somewhat with different observers. Thus, Darier, who was among the earliest to make use of it and who reports most favorably concerning its action, gives the patient a 5-per-cent. solution, to instil into the eye three or four times daily in simple conjunctivitis and as frequently as every half-hour in purulent conjunctivitis, he himself making an application of a 50-per-cent. solution to the everted conjunctiva once or twice daily. In blepharitis and suppurative diseases of the cornea topical applications of the stronger solutions are employed, and it is claimed that though an excessive amount accidentally come in contact with the cornea no injury will result as might be the case from solutions of silver nitrate. Bribosa employs it in the form of 5-per-cent. vapor and most highly

recommends this mode of application, believing it to be far superior to instillations and compresses.

In diseases of the lachrymal duct irrigating with 5- to 50-per-cent. solutions is claimed by some surgeons to bring about a healthy condition of the membrane and a rapid diminution of the amount of the discharge, provided there be present no pathologic condition of the bone (Darier, Messner, Wicherkiewics, Hotz); on the other hand, it is stated (Bistis, Bossalino) that, beyond a slight diminution of the discharge, there is but little improvement. Antonelli advocates the employment of 50-per-cent. protargol sounds, and his claims of excellent results from this method are supported by Bistis.

As a prophylactic measure in ophthalmia neonatorum, most of those who have employed it in the stronger solutions speak well of their results. Cramer reports its favorable employment in 200 cases and Engelmann, who made a comparative study with solutions of silver nitrate, using 20-per-cent. protargol, states that the latter proved superior to the former in every way. On the other hand, Von Ammon and Esmann do not speak so enthusiastically of its value, although it should be added that the latter employed it only in 1- and 2-per-cent solutions.

Concerning the pain and discomfort produced by the instillation or application of protargol there is almost as much difference of opinion as is held regarding its value in the treatment of ocular affections. A review of the literature shows that most observers believe it to be much less painful than solutions of silver nitrate, in fact, producing only a slight, transient burning, but others state that it is fully as painful, if not more so, and that in certain cases the pain from an application is so severe and prolonged as to give rise to the belief that an idiosyncrasy to the drug must exist.

Regarding the countries in which protargol finds its warmest advocates we have France first with Italy a close second. In the United States opinion is greatly divided, as was manifest in a discussion on the subject before the Section on Ophthalmology of the American Medical Association at the last annual meeting. Such men as Hotz, Sutphen, Jackson, Southard, and Connor reported the most favorable results from its employment; on the other hand, De Schweinitz, Wood, Clark, Allport and others were practically agreed upon the remarkable uncertainty of the drug, at times obtaining the most astonishing results from its use and again, under apparently similar circumstances, failing to produce the least improvement of the condition under treatment.

It can be seen, therefore, that the various observations, though covering a large amount of material and originating largely with men of considerable experience, are so widely contradictory in their results that the true value and therapeutic power of protargol in the treatment of ocular diseases cannot be definitely ascertained until much more extended experience is at hand. Of the practical value of the drug there is little question, but problems of idiosyncrasy, dosage, etc., must be solved to give protargol a definite place in ophthalmological practice.

ARSENICAL CONTAMINATION IN BEER.

In the Medical News for December 1st mention was made of a grave epidemic of peripheral neuritis occurring in the district of Manchester, England, due to arsenic-contaminated beer. The early press dispatches contained but few details, but the *British Medical Journal* and *Lancet* for December 1st, just received, give lengthy analyses of the conditions present from which we gather the following short account of one of the most interesting instances of universal poisoning of food and drink on record.

For the past three or four months clinicians in and about Liverpool have noticed an unusual prevalence of multiple neuritis occurring among beer drinkers. This was ascribed to the effects of alcohol until Dr. E. S. Reynolds, assistant physician to the Manchester Royal Infirmary, and visiting physician to the Manchester Union Hospital, became convinced that the features of the disease were different in many particulars from those observed in alcoholic multiple neuritis, and on the 21st of November announced before the Manchester Medical Society the startling fact that he had found arsenic in the beer used by many of the patients and that the neuritis was due for the most part to this toxic agent.

Dr. Reynolds' results have been amply verified since by Drs. Delépine and Tattersall, both of whom had suspected the nature of the peculiar poisoning and had found arsenic in the beer on November 16th, and reports from various parts of Lancashire and the Midland counties indicated that the poisoning was very widespread.

It is gratifying to learn that Drs. Delépine and Tattersall took immediate steps toward ascertaining the source of the poisoning, and on November 23d were able to notify the medical authorities of Manchester and of Salford that one

particular brewing house was using glucose which contained arsenic. Suffice it to say that the brewers themselves took prompt action in notifying all of their customers of the trouble.

From the clinical standpoint many interesting features of the epidemic were brought out. The general aspect of the patients was characteristic. The face was dusky and the eyes watery and the well-known puffiness of the under eyelids marked in many cases. The involvement of the skin was almost universal. This consisted of an irregular pigmentation, often ascribed to dirt, which at times closely suggested the bizarre coloring of Addison's disease. Herpes, erythematous and papular eruptions were common. In some there was a bran-like desquamation of the skin. In others the cuticle was thickened and the nutrition of the nails markedly altered. The nervous system was affected in all cases. Numbness, tingling, pain and cramps with final paresis or paralysis were distinct. Tremor was common. The knee-jerks were diminished or abolished in the greater number of patients. The upper respiratory passages were invariably affected. Coryza or distinct catarrh was universal. The digestive disturbances were of irregular occurrence; diarrhea, epigastric pain, anorexia and vomiting were present in varying degrees. The urinary organs did not seem to participate to any great extent in the poisoning.

It seems probable from the reports from various practitioners in the affected region that this form of poisoning has been going on for six months. Beer drinkers were those generally affected, although according to Dr. Kelynack's note, in one locality, drinkers of stout were also taken ill. The chief sufferers have been the poorer classes, as they are the main consumers of the cheaper varieties of beer. The chemical analyses of the beer showed that the amount of arsenic found varied from 1/100 to 3/10 of a grain to the gallon.

Of the source from which the arsenic was derived much might be said that would have a wide application. It is well known that sulphuric acid is universally used in the manufacture of glucose, which latter is an indispensable agent in the manufacture of beer. This sulphuric acid is generally prepared from iron pyrites which invariably contains a small percentage of arsenic. Thus the chain is complete, arsenic from the pyrites, to the acid, thence to the glucose and to the beer.

What bearing has this on the beer industries of this country? It is said that more glucose is made in the United States than anywhere else, but we are glad to be informed that the commercial glucose supplied to the American trade, largely by the American Refining Company of Chicago, is made from arsenic-free sulphuric acid. In an informal discussion at the last meeting of the Society of Chemical Industry, November 23, 1900, a number of chemists connected with brewing interests in this city came to the conclusion that inasmuch as the sulphuric acid of this country was a superior article that there was little likelihood of there being any danger lurking in American beers.

In view of the fact, however, that glucose is more widely used here than almost anywhere else, it is incumbent on our State analysts to make steadfast efforts to ascertain the presence of poisonous impurities; especially so, since the recent developments which have come to light on the use of glucose as an adulterant in the molasses industry.

ECHOES AND NEWS.

NEW YORK.

Building for Marine Hospital Service.—In Secretary Gage's estimate of expenses of the Government for the coming year $250,000 is asked for a Marine Hospital Building in New York.

Smallpox Situation.—A few more patients suffering from smallpox are found each day. The total number now reaches in the neighborhood of 60. At least 100,000 people have been vaccinated and sore arms are the rule throughout the city. Present indications point to a speedy end of the local epidemic, though isolated cases will probably come to light every now and then for some time to come.

Counter Prescribing and Poisonous Mixtures.—Oscar Epstein, druggist, of One Hundred and Sixty-third Street and Forest Avenue, sold some cough medicine which, it is alleged, caused the death of the infant child of a manufacturer of Trinity Avenue. The Coroner's physician for that district said that the druggist told him that he had been employed in a drug-store in Staten Island, where the proprietor manufactured a cough mixture such as was given to the child. This cough mixture, he told Dr. Reigelmann, contained 80 ounces of laudanum in every 420 ounces. Which is the more guilty person, the druggist who prepared the mixture or the father who bought it, is difficult to determine.

Obituary.—Dr. Edward A. Smith, of No. 105 East Eighteenth Street, died December 10th at the age of seventy-one. Dr. Smith was a member of the Union, Metropolitan, Racquet, and Players' Clubs, and of the Society of Colonial Wars.

Dr. George B. Banks, a prominent physician of Huntington, L. I., died December 11th from rheumatism. He was seventy-five years old. Dr. Banks was at one time President of the Board of Education, and was later Commissioner of Highways. He is survived by three daughters and a son.

Pure Food Movements.—The Board of Health recently opened a war on adulterated molasses which, according to Commissioner Murphy, is being sold throughout the city as the pure article. The action of the board is based on a movement in behalf of pure molasses, the agitation of which is now going on in New Orleans. Wholesale dealers say that so extensive has become the sale of the adulterated article that there is practically no call for pure molasses from grocers, who find larger profits by buying the adulterated article and selling it for the pure. Glucose is said to be the most common adulterant. Besides this admixture there are brands of molasses that are bleached with chemicals injurious to health.

New York Hospital Additions.—New buildings for the New York Hospital were opened last week. By the purchase of land and buildings on the west enlarged ground area was gained for them, and by rearranging the whole north front the possibilities of important additions were secured. The group consists of a private patients' building, a dormitory building for employes, ambulance departments, governors' building, and out-patient department. The largest building is the private patients' building. This is ten stories high, and, as it is equipped with modern elevators, the upper rooms are even more desirable than the lower ones. The first floor is used for executive purposes, the second mainly for the doctors, while the stories above are arranged for private patients, having reception rooms, pantries, bathrooms, and every comfort desirable. Many of these rooms are arranged in suites for those who desire complete accommodation; but there are a large number of single rooms for those who need privacy at a moderate outlay. On the upper floor are two operating-rooms, each with its separate etherizing-room, wash-rooms, sterilizing-rooms, nurses' rooms, etc., and each provided with its own ventilating plant controlled by thermostats in the rooms. At the rear of this building, separated from it and reached by special elevators from the yard, is an isolating department with toilet, baths, pantries, and disinfecting apparatus. It has its own heating and ventilating system, independent of the rest of the building.

Rating of Physician Candidates.—An important change in the manner of rating the standing of physicians who are candidates for positions in State institutions has just been made by the State Civil Service Commission. It has decided to accept in lieu of the examination heretofore required the examinations for license to practise medicine in this State conducted under the authority of the University of the State of New York, and to enter accepted applicants for such positions upon the eligible list in accordance with the ratings obtained by them in the examination for license to practise. In conformity with this determination an eligible list will be prepared on December 15th containing the names of persons whose applications have been accepted prior to that date, and new lists will be made up from time to time in the same manner whenever required. The positions are open to men and women. The salary in most cases is $600 a year and maintenance.

New York Academy of Medicine.—At the meeting of the Academy of Medicine held December 6th the following nominations of officers for the ensuing year were made: For president, Dr. Wm. H. Thomson, Dr. A. A. Smith, and Dr. Robert F. Weir; for vice-president, Dr. Virgil P. Gibney, Dr. Thomas Satterthwaite, and Dr. Chas. L. Dana; for secretary, Dr. Jno. H. Huddleston; for corresponding secretary, Dr. Louis Faugères Bishop; for trustee, Dr. A. A. Smith, and Dr. E. L. Herrick; for committee on admissions, Dr. Francis Torek, and Dr. Van Duzen Young. Polls are open December 20th from 8 to 9 P. M.

Surgical Section Nominations.—Nominations of officers for the Surgical Section of the New York Academy of Medicine were made at the meeting of December 10th, as follows: For chairman, Dr. John B. Walker and Dr. Charles L. Gibson; for secretary, Dr. Edward M. Foote was named. The election will take place at the meeting on the second Tuesday of January.

PHILADELPHIA.

Samuel D. Gross Prize.—The Philadelphia Academy of Surgery announces the Samuel D. Gross prize of one thousand dollars. No essay which the trustees deemed worthy of the prize having been received on January 1, 1900, they hereby announce that the prize will be awarded on October 1, 1901.

The conditions annexed by the testator are that the prize "Shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations, the candidates for the prize to be American citizens." It is expressly stipulated that the competitor who receives the prize shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery, and that on the title page it shall be stated that to the essay was awarded the Samuel D. Gross Prize of the Philadelphia Academy of Surgery. The essays, which must be written by a single author in the English language, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 219 S. 13th St., Philadelphia," on or before October 1, 1901. Each essay must be distinguished

by a motto and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

W. W. Keen, M.D.,
J. Ewing Mears, M.D.,
J. Chalmers Da Costa, M.D.,
Trustees.

Ambulance Surgeon Injured.—While the ambulance of St. Agnes' Hospital was conveying a patient to the hospital recently the front axle broke. Dr. O'Neill, the ambulance surgeon, jumped, but, becoming entangled in the reins, fell and severely injured one of his ankles.

Hospital Physicians Dine.—The fourteenth annual dinner of the Association of ex-Resident and Resident Physicians of the Philadelphia Hospital was held last week at the Bellevue, more than 50 members being present. The officers are: President, Dr. E. L. Dyer; Vice-Presidents, Drs. H. C. Wood and J. K. Lineaweaver; Secretary, Dr. E. R. Stone.

Faith Curists Sentenced.—Sheets and Sollenberger, proprietors of the "Beulah Orphanage," have been sentenced to three months in prison. The case grew out of the death of a seven-months-old child at the Orphanage last July. Sollenberger stated that he considered medicine a poison to the human system and that he believed in leaving ill persons in the hands of the Supreme Being. In passing sentence the Judge stated that the previous good reputation of the defendants had much to do with determining the length of imprisonment imposed.

Diseased Cattle Sent to New Jersey.—The Board of Health of Trenton has begun suit against the Trenton Abattoir Company to collect penalties for bringing diseased cattle into the State. Nearly a score of cows from Bucks Co., Pa., were condemned as tuberculous and killed. Some of the members of the Pennsylvania State Board of Health who were helping investigate the case state that New Jersey is practically made the dumping-ground for diseased cattle from this section of the State, because of the laxity of her laws.

Obituary.—Dr. Frederick W. Pleibel, one of the oldest practising physicians in the northeastern section of the city, died last week in the German Hospital. Dr. Pleibel was born in Germany. He came to this country in 1846, graduating from the University in the same class as the late Dr. Pepper.

Norristown Insane Asylum.—The Trustees of this institution are divided on the question of retaining Dr. Susan J. Tabor, resident physician of the female department. Charges of destruction of property and of lax discipline have been made and investigated. It is claimed that cliques of nurses existed and that deserving and capable new nurses have been obliged to leave on this account. As eight of the eleven trustees voting favored dismissal, an election has been ordered for January 4th. Members of the Board living in this city believe that such action is unwarranted.

Hygiene in Public Schools.—The Committee on Hygiene of the Board of Education has reported that the trial of screens to remove the dust from air before it is used for ventilating purposes has given very satisfactory results. This will likely lead to their introduction in all schools where blowers are used for ventilation. The inauguration of a system of physical training in the elementary schools is under discussion. The German-American Central Alliance has offered to furnish free of charge an instructor in calisthenics in any school named by the Board.

Suspension of Prolapsed Rectum.—Dr. Charles P. Noble, of the Kensington Hospital for Women, reports two cases of prolapsed rectum in which good results were obtained by suspension. An incision was made in the left inguinal region as for colostomy. The rectum was then brought up and sutured to the abdominal wall, preferably to the rectus muscle. Great relief is afforded by this method. Some constipation persists, this being more marked in one of the cases than in the other. Laxatives should be judiciously used to prevent this. Dr. W. J. Hearn also reports a similar case, operated upon in 1895, the patient being made very comfortable. In his case an assistant held up the bowel during the operation by the hand introduced through the anus.

Report of School Medical Inspectors.—A report covering the time from the inauguration of the system, January 1st to October 31st, has been made. The number of cases reported was 5876, of which 3446 were contagious. More than 1000 cases of defective vision were found. In addition to discovering diseases not before noticed, the report states that medical inspection has caused parents to exercise greater care in keeping at home children who otherwise would have been a menace to the health of their schoolmates. The inspectors have completed their organization with Dr. J. H. McKee as president, and Dr. F. C. Hammond as secretary and treasurer. Stated meetings will be held to discuss matters pertaining to school hygiene.

Mosquitoes and Malarial Parasites.—At the meeting of the College of Physicians, December 5th, Dr. A. E. Woldert read a paper giving the results of experiments in cultivating the malarial parasite in mosquitoes. The larvæ of the Anopheles were secured and the adult mosquitoes allowed to bite persons having malarial fever. In some instances the malarial parasites in their developmental stages were found when the mos-

quitoes were dissected. The Anopheles was found in every malarious district visited, but malaria was not present at every place where this species of mosquito was to be obtained. The Anopheles was found in the healthy Mt. Pocono region, which is 3000 feet above sea level.

Unusually Low Death-Rate.—The number of deaths during the week ending December 8th was 376, a very low mortality for this season of the year. This is in part attributed to the strict enforcement of laws regarding the reporting and isolation of cases of contagious disease, one physician being prosecuted during the past week, for failing to report a case of diphtheria. The corps of medical nuisance inspectors of the Bureau of Health is also to be credited with doing much to suppress disease epidemics. Smallpox has been practically stamped out.

Report of State Board of Health.—The annual report of the State Board of Health which has just been issued states that the most important subject of legislation at the present time is the institution of safeguards for public water supplies. The last Legislature recognized two facts: First, that the State has the right to exercise control over public waters and to forbid their pollution; second, the State Board of Health is the proper body to enforce this authority. This law applies only to cities of the first class and efforts are being made to have it extended. The report calls attention to the necessity for this, inasmuch as typhoid fever is a disease of the small village rather than of the large city. The epidemic at Cementon emphasizes the importance of a sanitary inspection of a water supply before its introduction rather than after its use. Cementon was rejoicing in a pure (?) spring water supply. An inspection showed sources of pollution on a stream supplying the dam from which water was pumped to the reservoir. Typhoid fever has made its appearance in all the families which have used this water. A sanitary survey of all the waters of the State is urged. Norristown is recognized as the principal source of pollution of the Philadelphia water supply, and the courts will be asked to interfere if the nuisance is not abated.

Concerning school directors the report says: "The law authorizing school directors to assume certain functions of a board of health is still on trial. The fact that during the past year only twenty-four school boards have availed themselves of this opportunity to aid in the protection of the public health would seem to indicate that it does not commend itself to the great body of school directors throughout the State. The entire number which have reported to the board as having assumed their new responsibilities is but fifty-six out of a possible two thousand seven hundred."

The total number of cases of smallpox officially reported as having occurred in the State during the epidemic which began in December, 1898, is 1429 with 18 deaths. The report calls attention to the fact that the State Board favors the placing of pulmonary tuberculosis in the class of contagious and notifiable diseases.

CHICAGO.

Epileptic Colony for Illinois.—After the members of the State Board of Charities voted last week to locate the new State epileptic colony, created by an act of the last Legislature, at Notchcliff, near Elsah, in Jersey County, conditional upon the people of that community agreeing to the conditions imposed by the Board in connection with locating the colony.

Bogus Medical Diploma Men Convicted.—A verdict of guilty was rendered in the United States District Court to-day against James and Thomas Armstrong for using the mails to defraud in connection with their diploma mill, the Metropolitan Medical College.

Chicago Sanitary Trustees.—Alexander T. Jones, the newly-installed president of the Board of Trustees of the Sanitary District, has hurled defiance at the local Democratic machine in terms regarded as a declaration of war without quarter. Mr. Jones said in substance that he would not be subservient to the wishes of the Democratic machine, but considered himself answerable solely to the people; and the utterance brought dismay to the hearts of "the gang," for Mr. Jones went further and promulgated plans which will reduce the annual expenditures of the Sanitary District by about $75,000.

Eye Disease in Chicago.—A disease of the eye, which in many respects resembles "pink-eye," is reported epidemic in this city. It is infectious, and is not confined to any particular part of the city or class of people. One explanation offered for the origin of the malady is that it is due to the clouds of dust which have been driven about the streets since the windy season set in.

North Central Illinois Medical Association.—The twenty-seventh annual convention of this body met at La Salle, December 4th and 5th. The program included discussions on various topics of special interest to the professions of medicine and surgery. A reception and banquet were given the delegates at the Harrison House by the doctors, dentists, and pharmacists of La Salle and Peru. Addresses of welcome were delivered by Mayor W. F. McNamara, on behalf of the citizens of La Salle, and by Dr. H. Ziehing on behalf of the local medical fraternity. The principal addresses of the evening were made by Dr. J. B. Murphy of Chicago and Dr. P. M. Burke of La Salle, President of the Association. The following officers were elected for 1901: President, Dr. F. O. Robinson, Wyault; First Vice-President, Dr. John Ross, Pontiac; Second Vice-President, Dr. Jane Reed Keefer, Sterling; Secretary and Treasurer, Dr. George Discus Streator.

Gives Warning of Smallpox.—The weekly bulletin of the Chicago Health Department gives

warning of the danger of smallpox and some figures on the prevalence of the disease. It quotes the federal health reports of November 23d last as showing 297 cases reported this year in Wisconsin, as against none during the same period in 1899. Out of thirty-seven infected States and Territories listed in the same table, in twenty-two a total of 4854 cases is reported this year, as against 1076 cases in the same period—that is June 29th to November 23d—last year. This is an increase of more than 350 per cent. In nine of these States, namely, Iowa, Nebraska, New Hampshire, New Jersey, North Dakota, South Carolina, Utah, Vermont, Wisconsin, no case of the disease was reported during the period of 1899. Illinois has 121 cases reported this year, as against seven last year; of the total 117 are reported from Cairo and four from Chicago. The bulletin continues: "These data indicate an impending epidemic of smallpox, which can be averted only by a general and individual resort to vaccination—the one sure and sufficient safeguard against this pestilence. Since the data of the federal report quoted the spread of the disease has rapidly increased—especially in the Northwest in territory tributary to Chicago. Returns to the Chicago Registrar of Vital Statistics show a total of 1751 deaths for the month of November, 1900.

GENERAL.

Owen's College, Manchester.—The late Dr. D. J. Leech, Professor of Materia Medica and Therapeutics in this institution, leaves £10,000 to endow a chair of materia medica and therapeutics.

A Virus for Rats.—Experiments of the Marine Hospital Service with the Danysz virus No. 2 seem to demonstrate it to be an excellent means for getting rid of rats and mice. Eight days seemed enough. In view of San Francisco's plague cases it is probable that the virus may be largely used.

Diphtheria Cases in School District.—Dr. I. C. Gable, County Medical Examiner of York, Pa., has made a thorough investigation of the diphtheria scare in the Broadbeck school district and reports 100 cases. He attributes the sickness to gross carelessness.

Bequest to Cleveland Hospital.—H. M. Hanna, brother of Senator Hanna, has given the Lakeside Hospital $81,580. He turned over to the trustees 1000 shares of Northern Pacific preferred stock valued at the present time at this sum.

Pan-American Medical Congress.—In view of the unsettled conditions of the yellow-fever situation in Havana it has been decided to postpone the meeting of the Pan-American Medical Congress. February 5, 1901, has been proposed as the most advisable date.

Yellow Fever in Mississippi and Louisiana.—Since the frost no new cases of yellow fever have been reported. From a series of investigations made of the towns about Natchez, Osyka, and Brookhaven, it seems probable that there has been much more yellow fever than has been supposed. Some five cases have been reported forty miles south of Natchez on the river in Louisiana. A large number of peculiar epidemic jaundice cases have been reported from McComb's Dam, Miss. Unless active measures are taken next spring may see a recrudescence of yellow fever.

Another Bubonic-Plague Death in San Francisco.—Another death from bubonic plague is reported from Chinatown. Quarantine against San Francisco will continue to be enforced at El Paso and on the western border of the State for an indefinite period. Louisiana and other Southern States have become alarmed at the prolonged existence of the disease in San Francisco and a general quarantine by all the Southern States may be declared against the infected city.

To Combine Toronto Medical Schools.—Definite steps are being taken to bring about the amalgamation of Trinity Medical College, Toronto, and Toronto Medical College. Representatives of the two faculties have held a meeting in the Premier's office, Toronto, and a committee composed of three members of each faculty was appointed to draft a definite basis of amalgamation.

Surgeons, Dentists and Veterinarians for the Army.—In the new Army Bill discussion amendments were passed bearing on the appointment of fifty volunteer surgeons, ranking as major, and of fifty assistant surgeons with rank of captain; thirty dental surgeons, of whom three should be chief dental surgeons, and a corps of veterinary surgeons.

Crime in the United States.—Criminology and sociology rest so largely on the medical aspects of individual psychology that some recent statistics on murder in the United States gathered by the Chicago *Times-Herald* is of special interest. The average yearly number of murders, computed on the number for the last decennial, in the different States in the Union is as follows: South Carolina, 221; Georgia, 381; Florida, 157; Ohio, 332; Indiana, 228; Illinois, 315; Michigan, 205; Wisconsin, 154; Minnesota, 159; Iowa, 202; Missouri, 362; North Dakota, 29; South Dakota, 45; Nebraska, 168; Kansas, 235; Maine, 18; New Hampshire, 9; Vermont, 6; Massachusetts, 96; Rhode Island, 52; Connecticut, 73; New York, 512; New Jersey, 120; Pennsylvania, 312; Delaware, 48; Maryland, 280; District of Columbia, 24; Virginia, 305; West Virginia, 87; North Carolina, 285; Kentucky, 398; Tennessee, 408; Alabama, 461; Mississippi, 317; Louisiana, 358; Texas, 1021; Arkansas, 305; Montana, 90; Wyoming, 22; Colorado, 252; New Mexico, 58; Arizona, 43; Utah, 57; Nevada, 39; Idaho, 27; Washington, 102; Oregon, 79; California, 422.

Metric System Coming.—The bill of Representative Shafroth of Colorado for the adoption of the metric system by the United States was

favorably reported last week by unanimous vote of the House Committee on Coinage, Weights and Measures. The bill is changed so as to make the system go into effect January 1, 1903.

Typhoid Fever at Galveston.—Galveston is reported to be threatened with an epidemic of typhoid fever. There is a great deal of sickness prevalent in the city and physicians say that the majority of patients have developed typhoid symptoms. A number of cases have occurred among persons living on the water-front. There are twenty-one cases now under treatment in St. Mary's Infirmary, and seven at the Sealey Hospital, and more would be at the hospital if rooms could be obtained. The outbreak and spread of the disease are due to the unsanitary condition of the city, and the impurity of the cistern water, the only means of supply for many families. Many persons are crowded together in buildings and tents that barely protect them from the inclemencies of the weather.

To Prevent Tuberculosis.—The German Department of the Interior has issued a set of instructions conveying compulsory precautions to be taken against the spread of tuberculosis in the empire. The instructions consist of seven articles, providing that doctors, under all circumstances where their patients have lung or larynx tuberculosis, must give written notice to the police as soon as the case in question has been diagnosed; that immediately after the death of a person from this form of the disease the room he used and his effects must be thoroughly disinfected; that professional women who lay out the dead must report at once in writing to the police authorities whether the disease was of the lungs or larynx; and that keepers of hotels, lodging-houses, asylums, or other public institutions, shall report immediately the appearance of the disease in the establishment under their control. Non-compliance with these regulations is subject to a fine of $35.70 or six weeks' imprisonment.

Cocaine Drunkenness.—Chief of Police Caster of New Orleans issued instructions to the police last week to arrest all persons dealing illegally in cocaine or suffering from cocaine drunkenness. The order said: "The constant use of cocaine has assumed large and serious proportions and is daily increasing to such an extent as to be a menace to public health. You are directed to notify the force under your command to use extreme diligence in enforcing the city ordinance against the use of cocaine and to make arrests. This menace is general throughout the city. This order must be strictly adhered to, and you will make written reports to this office of each offender arrested and from whom the drug was purchased, whether from a druggist or pedler." The complaints against the abuse of cocaine have been very loud for some time, thousands of persons, mainly negroes, using the drug and injuring themselves physically and mentally by it. Some drug-stores confine themselves almost wholly to the sale of cocaine, but the bulk of it is sold by pedlers in either pellets or in powder to mix with wine. Under instructions from the Mayor and Council the police will try to break up the abuse and banish cocaine from New Orleans.

Typhoid in the Army.—Surgeon-General Sternberg made public December 7th a report upon the origin and spread of typhoid fever in the United States military camps during the Spanish war of 1898, prepared at his instance by a board consisting of Major Walter Reed, Surgeon, U. S. A.; Major Victor C. Vaughan, Division Surgeon, U. S. V.; and Major Edward O. Shakespeare, Brigadier-Surgeon, U. S. V. The Surgeon-General prefaces the report by calling attention to the vast amount of work the medical corps was called upon to perform during the war, in order to cope with the tremendous increase of the army in the field, and comments upon the widespread prevalence of typhoid in 1898, 20,000 cases of this disease appearing among the troops encamped within the limits of the United States, from May until September of that year. A general summary of the conclusions reached by the Board indicates that during the Spanish war every regiment constituting the first, second, third, fourth, fifth, and seventh army corps developed typhoid fever, this being true of both the volunteer and regular commands. More than 90 per cent. of the volunteer regiments are shown to have developed typhoid within eight weeks after going into camp, and the fever developed also in certain of the regular regiments within three to five weeks after the tents went up. Typhoid became epidemic in all camps, large and small, North and South, and was found to be so widely distributed in this country that one or more cases are likely to appear in any regiment within eight weeks after assembly, whether on the march or stationary. It is also stated that, with typhoid fever as widely disseminated as it is in this country, the chances are that if a regiment of 1300 men should be assembled in any section, and kept in a camp having the most perfect sanitary conditions, one or more cases of the fever would develop. The Board condemns in general the methods of disposing of the excretions of the human body, holding that a lack of proper facilities in this respect was in large measure responsible for the prevalence of the fever in the camps. Infected water was found to be an unimportant factor in the spread of typhoid in the national encampments of 1898. The part played by flies in the dissemination of germs of the disease, however, was plainly evident. Except where urgent emergency makes it necessary, the Board urges that one command should not be located upon a site recently occupied and vacated by another. It is urged that the soldiers' beds should be raised from the ground, for the men are reported to have slept in dust piles possibly infected with typhoid germs; and also that the soldiers be made to remove their outer clothing at night, wherever possible.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, December 1, 1900.

ANNUAL REPORT OF THE COUNCIL OF THE ROYAL COLLEGE OF SURGEONS—PROF. CALMETTE ON ANTIPLAGUE SERUMTHERAPY—VITAL STATISTICS OF NEW SOUTH WALES—DECLINE OF THE BIRTH-RATE—THE "RATIONAL DRESS" MOVEMENT—THE MISTAKES OF THE WAR—FAILURE OF THE GOVERNMENT TO PROVIDE A MEANS OF BOILING WATER—SUCCESS OF THE MOSQUITO-PROOF HUT IN THE CAMPAGNA IN PREVENTING MALARIA—PROF. GRASSI'S SCHEME TO RID ITALY OF MALARIA—THE LEGAL PERILS OF MEDICAL PRACTICE—REVERSAL OF AN UNJUST VERDICT.

The annual report of the Council of the Royal College of Surgeons which has just been issued shows that there are 1221 Fellows and 17,510 Members, which is considerably more than half the names on the Medical Register. The experimental and chemical departments of the research laboratories of the Royal Colleges of Physicians and Surgeons have been completely reorganized. By the provision of a considerable quantity of apparatus they are now well equipped for carrying out research work. Here is prepared the serum for the treatment of diphtheria in the Metropolitan Hospitals. The mixed serum now issued averages 300 units per c.c. In the year 10,999 doses, each containing 4000 units, 24,408 doses, each containing 3000 units, and 725 doses, each containing 2000 units, have been supplied. In reference to the Library the supply of new volumes and journals has been fully kept up. The inflow of volumes is now estimated at about 1000 per annum, including journals and transactions, and the total number of volumes is well over 50,000. The library is particularly rich in the transactions of societies and in periodicals relating not only to medicine and surgery, but also to accessory sciences. The large illustrated works of zoology, anatomy, etc., are well represented. There is also a good collection of portraits of eminent members of the profession. The second Harben lecture was delivered at the examination hall of the Royal College of Surgeons and Physicians by Prof. Calmette, Director of the Pasteur Institute of Lille, who discussed antiplague serumtherapy. In all cases, he said, the infection whatever its mode of entry resulted in the multiplication of the plague bacillus first in the lymphatic channels, then in the blood. Even a few hours after infection the bacilli were found in the blood and in immense quantities in all the organs. The serum should provoke their rapid destruction by phagocytosis or bacteriolysis. Hence the slow absorption of serum injected subcutaneously failed to arrest the disease; but when injected into the veins the result was different. Four or five hours afterward the temperature dropped, rising again in eight or twelve hours and then dropping finally. The temporary rise corresponded to the period during which the bacilli were being removed from the circulation by the leucocytes. Antiplague serum contained a reacting substance which enabled the leucocytes and alexins of the blood to dissolve the bacilli. There was no danger attached to intravenous injections if given slowly and with care to avoid the introduction of air or septic particles. The serum was the best known remedy for curing plague. It was equally useful as a preventive, though, unfortunately, its action lasts only eight or ten days and therefore the injections should be repeated every week. At Oporto and Glasgow it had been established that inoculated persons who contracted the disease within the immune period had only slight symptoms and always recovered. The preventive injection, which should be made under the skin of the abdomen in a dose of 10 c.c., occasionally caused eruptions and sometimes joint pains, but these symptoms were transient. Above all the serum had the immense advantage of conferring immunity in a few hours.

The Government of New South Wales' report on the vital statistics for 1899 contains several items of interest. The population at the end of the year was 1,356,650, an increase of 22,810 on the preceding year. The marriage-rate was 6.89 per 1000, the highest since 1891. But the average number of children in a family has dropped from 5.26 to 4.04. The birth-rate was only 27.10, the lowest recorded. An investigation into the cause of this decline showed that (1) the proportion of fertile marriages is declining; (2) that among fertile women the birth-rate is diminishing; (3) that Australian women are less fertile than European immigrants. Illegitimate births have been steadily increasing and now amount to 7.16 per cent. of the total. The death-rate is 11.82, which is 0.61 below the mean rate of the last ten years. The death-rate from phthisis has fallen from 14 per 10,000 in 1899 to 11. Cancer shows an alarming increase; in 1860-64 the rates were 1.84 and 2.17 per 10,000 respectively for males and females: in 1895-99 they were 5.18 and 5.08.

The "rational dress" movement does not make much progress among our female population, but its disciples are enthusiastic and zealous in endeavoring to propagate their views. The "Rational Dress League" has just had a grand field night on the occasion of their annual public meeting. Believing that example is better than precept, the ladies gave a practical demonstration of the superiority of the knickerbocker over the ordinary skirt in active pursuits, whether work or play, especially in riding the diamond-frame bicycle. Attired in costumes of various tints the fair demonstrators afforded a curious study. Some looked charmingly pretty, others unfortunately did not; but all were actuated by a zealous desire to show the aims of the League. Viscountess Harberton addressed the spectators. She

said that the necessity for vigorous propaganda had been rendered greater by the almost universal adoption of the filthy and disgusting trailing skirt with which ladies swept up the dirt of the street, inconsiderately carrying it to the drawing-rooms of their friends. She would rather be hooted by unmannerly boys than run the risk of breaking her neck by riding a bicycle in ordinary costume. A medical man discoursed on the disadvantages of corsets and asserted that there was far too much material about the skirts of some members of the League. He did not advocate tights, but if something could be devised between tights and the superabundant accordion arrangement of present-day skirts it would be hitting a happy mean.

At the inaugural meeting of the Midland Pharmaceutical Society Dr. Green, who had recently returned from the front, gave an interesting address on his experiences and exposed the mistakes of the war from a sanitary standpoint. The greatest lack of the entire campaign was a means of boiling drinking-water—the only certain method of preventing typhoid fever. Filters were provided, but they were insufficient in number and liable to leakage. This was the greatest mistake of the whole campaign. No gun, no luggage, no machinery was too heavy or too cumbersome if required to assail the enemy, but for the defence of the troops against a foe far more deadly than Mauser bullets or shrapnel shells a few necessary boilers were too great impediments to be allowed. No man should have been allowed to drink unboiled water.

The experiment carried out by Drs. Low and Sambon of the London School of Tropical Medicine—living for some months in a mosquito-proof hut in the fever-stricken Roman Campagna—has been completely successful, and they have returned to London in unimpaired health. The spot where the hut was built was carefully selected by Italian experts as the most malarial part of the Campagna. An interesting fact in this connection is that 16 policemen, who visited Ostia at the time of the assassination of King Humbert in order to search for anarchists supposed to be hiding there, were all prostrated with fever, although only in the place for a few hours at night. Neither the English doctors nor their servants showed the slightest symptoms at any time. Professor Grassi now proposes to rid Italy of malaria by making every house in the affected districts mosquito-proof with wire-netting and insisting on all persons retiring inside at sunset and remaining in until sunrise—the hours during which the mosquito bites. Those already ill he will cure with quinine. According to him, one year ought to be sufficient to stamp out the scourge. But as some 2,000,000 ignorant people are concerned he gives himself five years.

The very unjust verdict by which a medical man was mulcted in £100 damages and costs for informing a relieving officer of the unsound condition of a woman's mind has been reversed in a higher court. I have already informed you of the facts. The woman had hallucinations, sent threatening letters to people, and thought herself bewitched. As she was a qualified pharmacist and was seeking a situation as such, the doctor rightly thought her a danger to the public and acted accordingly. Hence the monstrousness of the penalty imposed on him. The jury thought that some of the allegations made by the doctor were untrue and, while accepting the view that her mind was not sound, found that the doctor was actuated by malice. In the higher court the judges did not agree with the jury on any point and found that there was no evidence of malice.

VAGINAL HYSTERECTOMY—SEQUELAE OF HEPATIC HYDATIDS—THE THIRD CARDIAC SOUND—ANOMALOUS ECTOPIC GESTATION—REPEATED ECTOPIC PREGNANCY—INFLUENCE OF THE EYE ON THE DEVELOPMENT OF THE ORBIT—ETIOLOGY OF LAMELLAR CATARACT—ABDOMINAL RESECTION OF THE SIGMOID AND OF THE UPPER RECTUM—EVACUATION OF HIGH PELVIC ABSCESSES THROUGH THE ILEOCOSTAL SPACE—INCONTINENCE OF URINE IN THE FEMALE—CONTROL OF THE UTERINE ARTERIES IN ABDOMINAL HYSTERECTOMY.

A. H. N. Lewers, at the Royal Medical and Chirurgical Society, November 13, 1900, submitted the after-results of forty consecutive cases of vaginal hysterectomy for cancer. His custom has always been to examine most carefully under anesthesia each woman, in order to determine whether or not the neoplasm had extended beyond the uterus itself, and then to operate only when it is so confined. The point held is that extension by contiguity always means prompt local recurrence and large cancers, though local in the womb, usually have metastases. His patients have been under his care for two to seven years after interference and present the following statistics: Twelve cases have been up to the present without recurrence; eighteen suffered from return of the growth and four died; three had passed out of his knowledge; two remained without settled diagnosis; and one had primary tuberculous ulceration of the cervix uteri. Omitting one case in which about one year had elapsed, the other eleven gave very satisfactory results for periods ranging from two to seven years or over. His conclusions are that vaginal hysterectomy is a most promising operation when done early enough, and that early diagnosis rests upon careful examinations and minute attention to cases giving a history of irregular bleeding at any period of life and particularly about the menopause. If women better understood the possibilities behind this symptom many would seek advice early enough to receive prolonged and in a few instances permanent relief.

N. Dalton, at the Clinical Society of London, November 9th, discussed the following sequelæ of a case of hydatid cysts of the liver. The girl at the age of eleven years was admitted to the Great Ormond Street Hospital in the service of Dr. Barlow for hydatid cysts of the liver. She then passed hydatids *per rectum* and coughed up bile. Complete freedom from symptoms followed until her sixteenth year when she came under the writer's care for ascites at the King's College Hospital. Paracentesis was required every two weeks to relieve the symptoms. Finally an exploratory operation was done in the hope of finding some remnants of the old cyst or other remediable cause of the ascites. Only the adhesions about the site of the old hepatopulmonary fistula were present and the abdomen was therefore closed. During the succeeding two weeks two paracenteses were necessary, but thereafter only the lower hypogastrium contained fluid and the rest of the abdominal cavity appeared to be obliterated by adhesions. For the next five years this continued until a ventral hernia developed in the laparotomy scar and at her twenty-third year caused a fatal septic peritonitis. Post-mortem were found (1) the old cyst cavity opening above by the fistulous remnants into a bronchiectasis and below into a dilatation of the gall-duct; (2) adhesions thickening the mesentery and omentum and obliterating the upper part of the peritoneal cavity; (3) turbid fluid in small quantity in the hypogastrium; (4) pus foci elsewhere in the cavity; (5) thickenings of the capsule of Glisson; (6) cirrhosis extending inward from the capsule. Thus almost complete cure of the ascites appeared ascribable to the numerous adhesions, which mechanically obliterated the cavity and by establishing rich collateral anastomoses between the portal and parietal venous systems relieved the congestion of the liver itself and of its portal blood-supply. The adhesions were probably excited solely by exposing to the air, when the laparotomy was done, the ill-nourished endothelial cells of the peritoneum, precisely as when tuberculous inflammation yields to such access of the air to it. Since the cyst had been virtually cured during the last few years of life the ascites had been due to the cirrhosis which continued as an active process. Probably the ascites of all cirrhoses would cease if good collateral circulation could be excited by adhesions.

T. S. Wilson discussed the diastolic cardiac sound causing spurious reduplication of the second sound at the apex, often called the third sound of the heart. In his opinion the underlying causes appeared to be as follows: (1) This third sound of the heart is not produced by the inrush of blood into the ventricle, although in some cases of mitral stenosis the flow causes a murmur, which is, however, synchronous with the diastole; (2) during the expansion movements, probably, the valve segments are kept tense by the muscular action, but at the moment of relaxation are free to move. If, therefore, a powerful enough stream of blood were still flowing through the valve at this moment of relaxation it would vibrate the valve curtains and cause an audible sound; (3) if this view be correct, the third sound means that the auricle is unable to empty itself as fully or as quickly as normal; (4) such delay in the flow will occur (*a*) when the mitral valve is stenosed and (*b*) when the ventricle cannot in expanding draw off the entire auricular contents; (5) therefore we would look for the third sound (*a*) in mitral stenosis, (*b*) in dilatation of the auricle, and (*c*) when the ventricle is too feeble to empty the lesser chamber. Cardiographs were shown and notes of an autopsy tending to support these views. In life the girl had shown pericarditis, a loud third sound and mitral regurgitant murmur. Instead of a short rise in the cardiographic tracing just at the end of the diastolic decline and during ventricular relaxation, there was a high, pointed rise almost as high as the ventricular rise itself. Apparent all over the heart, it seemed to show that during the relaxation period the ventricle filled up and then partially emptied itself. Ulcerative endocarditis caused death. The mitral valve was found *post-mortem* not stenosed, but certainly incompetent. The ventricular capacity was normal at ninety, while the auricle had one hundred and sixty-four cubic centimeters. Pericarditic adhesions had probably kept the ventricle from dilating and the flow of the large quantity of blood from the auricle had caused the temporary rise in the curve.

E. O. Croft, at the Obstetrical Society of London, November 7th, detailed a case of anomalous ectopic pregnancy. By abdominal section the sac and its contents were removed which by rupture caused violent hemorrhage, yielding to ligation of the broad ligament. Death by exhaustion followed. At the necropsy no peritonitis was present and the organs were removed for examination. Before rupture the sac had contained the whole fetus about four months old, membranes, placenta and amniotic fluid, but no blood, fluid or clotted. Its relations were those of an ovarian tumor with a short pedicle, with follicles over its surface resembling the Graafian follicles, but no structure corresponding to the ovary could be found. The tube was normal. The uterus and its appendage of the opposite side were normal. No ovarian tissue was certainly diagnosed in the tumor walls, but the case appeared to be an ovarian ectopic pregnancy.

A. H. Lewers reported a twenty-nine-year-old patient who had never been normally pregnant, but twice had had tubal gestation. In March, 1894, the left appendage was removed, and the tube found to contain a two-month-old fetus at the point of threatened abortion. The ostium of the tube was patent, but not dilated. In May, 1900, she had a complete tubal abortion on the right side, and that tube and ovary were taken out. Complete recovery followed. The ostium of the second tube was widely dilated. Reference was made to J. H. Ferguson's recent paper on this subject in which it is stated that

consecutive ectopic pregnancy is not rare in literature, but only fourteen repeated laparotomies for it are reported. The interval between the first and second impregnations varies from six weeks to five years. Hence this case of the author seems unusually long, over six years. Bland Sutton said that the diagnosis of ovarian ectopic pregnancy rests on two factors, pressure of undoubted ovarian tissue and of positive fetal substance therein. In the absence of demonstrated ovarian stroma and cells, he is inclined to be very skeptical of any so-called ovarian ectopic pregnancy.

W. E. Thompson, at the Ophthalmological Society of the United Kingdom, November 8th, read a paper on the disputed question as to whether the eye influences the growth of the orbit. Rabbits were anesthetized and one eye enucleated and later after the animals were full-grown they were killed. Measurements showed that there was a great difference between the two orbits; in all dimensions the normal exceeded the anophthalmic side by fifteen per cent. in the fresh and ten per cent. in the macerated skull. The application of the paper is at once important, because artificial eyes should be promptly inserted.

N. G. Bennett read a few notes on the cause of lamellar cataract, claiming that there is a relation between dentition and nutrition and this disease. Reference was made to the paper of Bernard Duband and Treacher Collins stating the measurements of lenses during life and after removal. Accepting these ophthalmoscopic and direct observations as authoritative, it became apparent that the lens is attacked by the disease either at or just before birth, or if the onset is later the part of the organ diseased seems to correspond with the periphery of the lens at or before birth. He then described minutely the teeth of twenty-two cases of lamellar cataract he had collected, in two classes on the basis of the degree the enamel had been affected. In each class, taken in conjunction with the dates of calcification as fixed by Röse, the disease appeared to have begun after birth, the period in one class being variable and in the second class about two years later. The exact cause of these conditions has long been a matter of dispute. Referring to a large number of examples of hypoplastic teeth he pointed out that in cases free from lamellar cataract the disease had very evidently begun at much later and irregular periods. When the history is definite it seemed that most of such cases had suffered from exanthemata, whereas the others had had irregular sicknesses like convulsions, malnutrition, etc. Sometimes the teeth would have two or more horizontal depressions, corresponding with the same number of attacks. The inference is that lamellar cataract is a disease of infancy, probably due to malnutrition. The developmental similarity between the teeth and the lens may be significant.

R. Morison, at the British Gynecological Society, November 8th, described several new operations for gynecological conditions. (1) Abdominal resection of the sigmoid or upper portion of the rectum, applicable to left suppurative salpingitis affecting the rectum and to cancer of the sigmoid mistaken for disease of the ovary. Its steps are as follows: (*a*) The diseased bowel is resected; (*b*) into the proximal stump is tied a glass bobbin carrying distally a rubber tube, which is passed through the distal stump of the bowel and out of the anus; (*c*) traction then telescopes the upper into the lower piece of bowel; (*d*) the distal stump is next tied very tightly to the bobbin just to the anal side of the cut edge of the sigmoid; (*e*) resumed traction now produces a moderate intussusception which is secured by Lembert sutures. In seven to nine days the sloughing bowel and bobbin come away. He has done the operation fourteen times, twice for complicated salpingitis and twelve times for malignant disease. The mortality was 50 per cent., which may be decreased by avoiding doing the operation with a loaded colon. A primary colostomy will avoid this blunder. His second operation is for certain forms of parametric abscess. Such processes may be in the floor of the broad ligament and pointing into the vagina, or in the course of the broad ligament between the two leaves of peritoneum and pointing often above Poupart's ligament, or in the pelvic and iliac glands out of reach from the vagina. He had seen two fatalities follow evacuation of the pus by abdominal section. He has successfully performed the following operation twenty times: Corresponding with the middle third of a line from the middle of the iliocostal space behind to the symphysis in front a three- or four-inch opening into the abdomen is made. Through this the diagnosis is confirmed by palpating the uterus and its adnexa and locating the boundaries of the abscess. The incision is next extended backward to correspond with the prominence of the focus. With the left hand within the abdomen as a guide, the right hand bluntly opens the abscess, free drainage and suitable suture complete the process. His next point was the simplicity and value of first clamping and cutting, then tying the uterine vessels in abdominal hysterectomy. For a patulous and incontinent female urethra he had satisfactorily followed this method: Half-way between the umbilicus and the symphysis a one-inch incision down to the peritoneum is made. The patient is then put into the lithotomy position and an incision encircling the urethra made, joined by one in the long axis of the vagina extended beyond the neck of the bladder. The flaps were dissected off and the urethra and neck of the bladder were freed absolutely and on all sides. Next between the abdominal parieties and the serosa an artery forceps was forced gently down into the vagina. Here it seized the urethra and drew it up into the abdominal wound, where it was secured by sutures. The bladder was drained by a catheter left *in situ* for eight days. The dressings during this time had kept dry and when the catheter was withdrawn it was supposed the bladder might be continent sufficiently to per-

mit a regular use of the catheter. But the organ will hold one and a half pints against cough and ordinary exertion, but can be emptied at will.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE—SECTION ON PEDIATRICS.

Stated Meeting, Held November 8, 1900.

Thomas H. Southworth, M.D., Chairman.

Pyelonephritis.—Dr. Louis Fischer presented a patient who had suffered for years from a purulent condition of the right kidney and who had recovered after nephrectomy. The child, now a girl of twelve, had been healthy from birth until the age of four and had acquired her teeth and learned to walk and talk at the usual time. When four years old she suffered from varicella and then from measles. During the convalescence from the measles it was noted that the urine was frequently cloudy. Ever since that time the child has suffered from recurring attacks of fever often ushered in by chills. This fever did not seem to be intermittent, but was irregularly continuous and the child's general condition was very poor. She was treated for malaria, because of the recurring chills and fever, but without effect. When she came under Dr. Fischer's care a large tumor could be felt in the right ileocecal region, extending from the margin of the liver well down on the crest of ilium. This tumor was hard; evidence of fluctuation could not be obtained. The urine contained albumin and casts, some red blood-cells, but never any pus cells. It seemed probable that the tumor had some connection with the right kidney, but the possibility of its being ovarian in origin was to be borne in mind. The patient presented the usual symptoms of pyelonephritis. There was considerable gastric disturbance, marked anorexia and obstinate constipation.

Operation.—At the operation, which was done through the abdomen instead of through the loin because of the doubt as to the origin of the tumor, the pelvis of the right kidney was found to be a huge pus sac. Tubercle bacilli were not found, nor could any other microbe be demonstrated. Concretions had formed along the abscess-wall. These seemed to be due to secondary calcification of broken-down material within the pus sac. The condition was evidently simple pyelitis. The kidney itself was affected by an interstitial nephritis. The post-operative improvement has been very marked. The other kidney had compensatory hypertrophy and the patient is now passing two pints of normal urine a day. A very interesting symptom that has developed since the operation is the occurrence of ribbon-like stools due to narrowing of the lumen of the gut by inflammatory adhesions. This does not, however, interfere with the girl's general health, nor does it give rise to serious constipation. The condition is not growing worse. The adhesions show no signs of continued contractility and so further narrowing of the lumen of the colon seems improbable.

Surgery of Pyelonephritis.—Dr. S. Marx who operated gave his reasons for choosing the transperitoneal route as follows: (1) Because the tumor was so large that he doubted whether the ordinary lumbar incision would suffice for the delivery and complete removal of the tumor, even if it should prove to be, as was suspected, of kidney origin. (2) There was some doubt as to the diagnosis of the kind of tumor that was present. The possibility of its being an ovarian tumor, either cystic in nature or one of the teratomata, could not be excluded. (3) Physical examination showed that the tumor was attached to the liver and if the adhesions were to be broken up without subjecting the patient to unnecessary risk, the abdominal route would give much more opportunity to work by direct vision. The mortality for the removal of purulent kidneys by the abdominal route in children is more than 50 per cent.

Frequency of Pyelitis.—Dr. Jacobi in discussion said that pyelitis is not so uncommon in children as is usually believed. Some years ago Dr. L. Emmett Holt reported a series of cases and pointed out that their occurrence was more frequent than was generally believed. All kidney diseases in children are more frequent than are imagined. The interesting question in this case is, What was the original cause of the pyelitis? Very frequently pus in the pelvis of the kidney develops as a consequence of the presence of a renal calculus. Certain concretions were found in this case, but they were not considered to be primary calculi. If on being examined, however, they proved to have a uric-acid nucleus it would then seem clear that the calculus was the primary condition in the case. Infants very frequently pass an excess of uric acid during the first two or three weeks of life and the characteristic uric-acid stain on the napkin is usually easy to find. The uric-acid infarcts found in the kidneys of children who die very young point to the excess of this substance. These infarcts emphasize the necessity for giving the child an abundance of liquid during the first days of life so as to aid in flushing out the kidneys.

In closing the discussion Dr. Fischer said that pyelonephritis in children sometimes seems to originate from vulvovaginitis. The micro-organism which causes the external inflammation succeeds in working through the bladder to the ureter and thence to the kidneys. Dr. Baginsky claims that pyelonephritis in children is practically always due to the bacterium coli commune, which probably finds it way into the kidney through the intestinal walls.

Enlarged Thymus.—Dr. Henry Heiman presented a patient with an enlarged thymus. The

child is but three months old and has been in good health ever since birth, which was instrumental in character. Its cry is the noticeable feature of the case. When the child becomes irritable there is a peculiar persistent whine during which cyanosis develops. Physical examination is negative, except for an increased area of dulness over the thymus region, especially over the right lobe of the organ. After this discovery it was found that the lymphatic glands of the neck were somewhat enlarged. This probably represents one of the cases that will prove in after life, if the child should live, to be unsuitable for anesthesia; as the status lymphaticus of such patients usually brings with it a tendency to adenoid overgrowth in the pharynx, this fact must be borne in mind. Two cases of sudden death at Mt. Sinai Hospital within the last few months have proved to be associated with enlarged thymus. In at least one of them hypertrophied lymphoid tissue was found in the intestinal tract.

Dr. Jacobi said that an enlarged thymus cannot always be demonstrated by percussion. In one instance where he was called to see a child that had died suddenly a short time before percussion failed to reveal the presence of enlarged thymus and yet the autopsy proved that it was present. It is important in percussing for enlarged thymus to turn the child over on its face, and have it held up in the arms of the nurse so that percussion can be practised at the favorable moment when gravity brings the enlarged thymus forward against the chest-wall. In cases of enlarged thymus a systolic murmur can often be heard in the median line at the second rib. Growing inspiration is not an unusual symptom in cases of enlarged thymus, but, of course, it may occur in other conditions, as in craniotabes.

Dr. Kerley said that the sudden death which occurs because of enlarged thymus frequently comes on without any preliminary symptoms. The child suffers from a single convulsion and then dies. The most faithful investigation of the child's history will frequently fail to reveal the slightest symptom that may point to the existence of an enlarged thymus before the moment of the fatal issue. One child seen by him was seized with a convulsion while nursing and promptly died. The thymus was found at the autopsy to be four or five times the normal size, yet it had not occasioned a single symptom that would have previously called attention to its presence.

Dr. Libman said that he has recently seen four cases of sudden death in which an enlarged thymus was found at autopsy. One of them died in a dispensary and proved on section to have the status lymphaticus. A second was taken with an attack of laryngismus stridulus, threw its head back and promptly died. An enlarged thymus was found, but the status lymphaticus was absent. Two other patients suffered from enlarged thymus after extensive burns. In each of the cases the children passed from quiet sleep to death without a struggle. The nurse had seen each of the patients within a quarter of an hour before death and they seemed perfectly well. They were found dead, neither outcry nor change of position having been noted. In each patient edema of the thymus gland was found to exist.

Unusual Infantile Scurvy.—Dr. Francis J. Murray read this paper which will appear in a subsequent issue of the Medical News.

Diet and Scurvy.—Dr. Kerley reported histories of twenty-four cases of scurvy that have occurred in his experience. In twelve of these cases the children were being fed on good artificial food formulæ and the diet was above suspicion. In two cases that occurred recently one patient was being fed on raw, the other on Pasteurized milk. The affection is not due to the special character of the food given, but to its malassimilation. The proper food elements for nutrition are not absorbed from the digestive tract in the amounts necessary for healthy metabolism.

Dr. Walter Lester Carr said that the most interesting thing about Dr. Murray's case is the fact that the mere addition of fruit-juice without any special change of diet led to prompt recovery. This question of the necessity for a change of diet, as well as the addition of fruit-juice, is as yet in dispute. Clinical experience seems to indicate that the addition of fruit-juice without any other change of diet suffices to relieve the symptoms.

Acute Rheumatism in Children.—Dr. Henry Heiman said that there has been a good deal of discussion in recent years as to the cause of rheumatism. So many theories of causation have been suggested that there exists more confusion than ever as to the actual etiology of the disease. Some years ago Prout suggested that it was due to an excess of lactic acid in the body. This was a gratuitous theory, however. There is no sure test for the quantitative presence of lactic acid in the blood. More than this, physiology has not yet made certain what is the normal formula of lactic acid in the tissues. Haig suggested uric acid as the cause of rheumatism. Other observers have not been able to confirm Haig's observations as to the presence of an excess of uric acid in the blood of rheumatic patients. Heiman in a series of cases carefully investigated for the purpose never found an excess of uric acid in the urine of those suffering from rheumatic arthritis. The question of the nervous origin of rheumatism put forward by certain American neurologists is no longer considered tenable. The occurrence of rheumatism with special frequency during damp weather led to the formulation of the theory that the disease was miasmatic in origin and that it was due to some organic poison that occurred in the atmosphere during damp weather.

Rheumatism as an Infection.— There are many qualities of rheumatism which point to its infectious nature. Its clinical course, its prodromal

symptoms followed by a rise of temperature, sometimes accompanied by a chill and certain tendencies to self-limitation, class it with the infectious fevers. The pathological changes found in the organs of patients who die during an acute attack of the disease also indicate its infectious character. A certain amount of cloudy swelling has been noticed and an enlarged spleen, hemorrhages into various organs, etc. The changes in the blood are those which occur during infectious fevers as the result of the presence of the toxins of bacteria on the circulation. Singer of Vienna found in a series of cases of rheumatism that a number of micro-organisms were present in the joints and on the heart valves of rheumatic patients. Their morphology was that of the pyogenic microbes. His conclusion was that rheumatism was really a modified pyemia due to the invasion of the system by an attenuated pus micro-organism.

Rheumatism in Children.—In children during an attack of rheumatism there is a lessened liability to joint complications. Frequently the disease causes only pain and as a result rheumatism in children often masquerades under the disguise of harmless growing-pains. At its worst the disease is seldom so severe as in adults and there is less tendency to the development of pyrexia. There is, however, a considerably greater tendency to the occurrence of metastases of the rheumatic virus to various parts of the body. Erythemata, rheumatic purpura, tendinous nodules of inflammation, pericarditis and endocarditis are much more frequent than in the adult. The commonest complication is endocarditis, which children very seldom escape unless the greatest care is exercised in the treatment of attacks of rheumatism. During the course of rheumatism, peptonuria is frequently found. It is caused by the destruction of leucocytes within the system and the elimination of their products through the urine.

Pseudorheumatism.—A number of affections that have been looked upon as rheumatoid in character and have even been given the name of rheumatism should with our modern knowledge of the disease be entirely excluded from the category of rheumatic affections. Formerly one spoke of gonorrheal rheumatism and of the rheumatism which complicates scarlet fever, typhoid fever, erysipelas and other diseases. Now it is known that the arthritis which occurs during the course of these diseases is really due to the specific microbe of primary affection. Our present knowledge of the microbiology of rheumatism shows that, in addition to whatever microbe may play a rôle in the etiology of the disease, the predisposition of the individual is an important adjuvant. Soil, climate and heredity serve to create the predisposition which leads to rheumatic infection.

Occurrence of Rheumatism.—Rheumatism occurs very rarely in patients under three years of age. Some cases have been reported by Jacobi, Chapin, Holt, Henoch and others, in children younger than this. It must be remembered that most cases of so-called rheumatism which develop under one year of age are really scurvy. A few cases of genuine rheumatism have, however, been reported even in nurslings and in some cases it has been noted by competent careful observers that a mother suffering from an attack of acute rheumatic arthritis has given birth to a child with unmistakable symptoms of the same disease.

Treatment.—In children, as in adults, the best remedy for rheumatism is some form of the salicylates. Usually salol or salipyrin will be found effective. Although the salicylates are a specific for rheumatism they fail to cure in certain instances. Other remedies will then have to be employed.

Prophylaxis.—It has been found that quinine given in comparatively small doses will prevent relapses of malaria. It has therefore been suggested that relapses of rheumatism might be forestalled in the same way. Dr. Heiman has tried this method during the past year in a certain number of cases with excellent satisfaction. There is no mention in medical literature of prophylactic treatment for rheumatism, except a recent suggestion of Ewart's, who proposes to use the salicylates somewhat in the same way. Prophylactic treatment consists in the administration of three to five grains of some salicylate for one week of each month for a number of months after the occurrence of an attack. Undoubtedly, as is the case with malaria, the microbes that cause rheumatism lurk somewhere in the system. The salicylates act as antiseptics in the circulation; they kill the bacteria, neutralize toxins, and thus protect the heart. It is well known how liable children are to recurrences of rheumatism and it is also well known how much each recurrence lessens the chance of escape from serious heart complications. This prophylactic treatment therefore should prove a great boon.

Rheumatism and Trauma.—Dr. Jacobi said that while rheumatism is almost certainly microbic in origin, there is no doubt that certain conditions especially predispose to its occurrence. It is worthy of note that there is much more rheumatism of the joints of the lower extremity than of the upper extremity. This seems to be due to the fact that the more frequent occurrence of trauma in the legs provides a lowered resistance where the microbes of rheumatism find a ready lodging. Seventy-five per cent. of the cases of acute rheumatic arthritis occur in the lower extremity. It is important, therefore, to prevent trauma in children who are especially predisposed by heredity or a previous attack to the occurrence of inflammatory rheumatism. Charcot first called attention to this fact and it is a matter of common clinical experience that after fractures and wounds about the fingers, as the result of impediments to the circulation, micro-organisms so often present in the circulation find a

ready lodgment. The same conditions hold for tuberculous osteitis and arthritis. It is not an easy matter to prevent trauma in a healthy boy, but even slight injuries must be taken care of and as far as possible avoided.

The Pharynx and Nose in Rheumatism.—Long before there was question of microbes in rheumatism and their possible entrance through the tonsils, the connection between tonsilitis and rheumatism had been observed by clinicians. Great care should be taken of the throats of children who are liable to rheumatism. Adenoids should be cared for and if any nasal discharge exists it should be treated. Large tonsils should be removed and nasal irrigations should be employed more often than at present. Under the influence of proper nasal irrigation small adenoid growths in the pharynx disappear. For nasal irrigation no syringe or fountain irrigation apparatus should be employed, but simply a cup containing the irrigating solution. The maintenance of a good cutaneous circulation will stimulate the system and relieve a laboring heart. Patients liable to relapses of rheumatism, as those suffering from chronic tuberculosis, whether they be children or adults, should be advised to take a cold sponge bath every morning and then a good rubbing afterward.

Salicylates Not Specifics.—Dr. James J. Walsh said that it must be borne in mind that the idea, originally so prevalent of the salicylates as specific remedies for rheumatism, had been abandoned by most foreign therapeutists. At the Charité Hospital in Berlin, where the salicylates were first introduced, they are no longer employed in the treatment of rheumatism in two out of the three clinics. The salicylates do not influence the course of the rheumatism. They relieve pain, lower the temperature and make the patient comfortable. Prof. Pribram, in his monograph on rheumatism, collects the statistics of parallel series of hundreds of cases treated by the salicylates and by other remedies. Patients treated by the salicylates were not on the average able to leave the hospital any sooner than those treated by other remedies. The salicylates are depressant drugs. To use them for the purpose of prophylaxis against rheumatism would seem to be a mistake. As to the specific microbic cause of rheumatism it is probable that while rheumatism is surely an acute infectious disease it is not due to any form of organism which is at present known. Singer's work, which would seem to make rheumatism a modified pyemia due to attenuated pyogenic germs, has been completely discredited not only by the Vienna school, but by the labors of many other investigators. Widal declared at the last Paris Congress that rheumatism was surely an infection. Fluid taken from the joints of rheumatic cases shows the presence of many polynuclear leucocytes. These cells are an index of Nature's reaction against some infective material. Widal has tried to obtain cultures from the joint fluids of fifteen cases of rheumatism, but without success. The arthritic fluid was put in contact with every medium known to modern bacteriology, yet failed to produce a growth.

Rheumatism a Household Disease.—Dr. Oppenheim said that rheumatism is distinctly a household disease. It is rare to have a single individual suffer from it where many people are living together. In about 70 per cent. of the cases there is an hereditary element in the etiology of rheumatism. Cheadle says that if rheumatism occurs on both sides of the house in the ancestors there is marked tendency to serious, recurring rheumatic storms during life. At the first manifestation of a predisposition to rheumatism the general health should be cared for. It will be found that it is at times when the general health is at a low ebb that rheumatic attacks occur.

Dr. Kerley said that he hesitates about giving the salicylates for prophylactic purposes, because of their tendency to depress. To two patients in whom a marked tendency to the recurrence of rheumatism existed he gave strychnine and iron for alternate weeks with salicylates, but was not satisfied with their action. One of his patients fell ill of rheumatism with severe endocarditis during the course of the week in which he was taking salicylates. He believes that the method suggested by Professor Jacobi of stimulating the system and improving the circulation by douches of cold water, followed by rubbing down, is much more likely to do good.

Dr. Heiman in closing the discussion said that Prudden has shown that the salicylates when taken into the system produce a very definite effect upon the cell protoplasm and prevent the migration of leucocytes. Clinical experience seems to show that it will be of use in preventing rheumatic relapse. Care, of course, must be exercised in giving the drugs, especially where any kidney affection exists. Failure to eliminate the salicylates and their retention in the system lead to their being split up with the production of carbolic acid.

BOOK REVIEWS.

Forty Years in the Medical Profession, 1858-1898. By John Janvier Black, M.D., Member of the College of Physicians, Philadelphia. J. B. Lippincott, Philadelphia.

This rather unique book, neither wholly medical nor wholly literary, appeals to us from a very human standpoint. It is the mantle of experience which a wise and observing man is letting slip from his shoulders. The book as its title proclaims, records the personal relations of a busy physician to the discoveries and signs of the times.

Dr. Black had evidently in his youth the picture memory that retained sharply-defined images, and it is with almost photographic clearness that he reproduces the scenes of his student days, the

clinics of Pancoast, Gross and Agnew in Philadelphia, with the strong personality of the men. He has also that seeing eye which is the heritage of experience, and has traced through the rise and progress of bacteriology, antisepsis, serumtherapy, and the multiple new theories of medicine, the true thread of progress. In short, throughout the series of half-essay-like, half-reminiscencing chapters on the medical life of the last half century, he presents in a naive, friendly, quite conversational tone the actual practical benefit that he has derived as a country practitioner, from this progress of medicine. And we cannot help feeling that many a man strained to distraction with new theories, new medicines, and new methods, might find a certain calm and rest in reading this readable book, and discovering among conflicting theories what a common-sense practising physician had tried and had not found wanting.

A Manual of Materia Medica and Pharmacology. By David M. R. Culbreth, Ph. G., M.D., Professor of Botany, Materia Medica and Pharmacognosy in the Maryland College of Pharmacy; Associate Professor of Materia Medica and Pharmacognosy in the University of Maryland Medical and Dental Schools. Second Edition. Lea Brothers & Co., Philadelphia and New York.

In the rapidly enlarging scope of the teaching of students of pharmacy and of medicine a number of reliable text-books of the kind under consideration have been published. Culbreth's book represents one of the best of its kind. For the student of pharmacy it is an invaluable guide and no pharmacist should be permitted to practise his profession unless he possessed a thorough acquaintance of the facts which are here gathered. He cannot afford to know less. For the student of medicine, however, the work is not essential, yet it might well serve as a foundation on which to build a structure of future studies. As anatomy is the necessary groundwork for efficient progress in physiology, surgery and a knowledge of abnormal states, so the materials which are utilized in the treatment of a disease should be thoroughly known in their various relationships, botanical or chemical, in order that comprehensive work can be done in the subsequent study of the action of drugs and the application of such activities in the modification of abnormal and aberrant physiological states. From this point of view such a work would be most eminently useful in the first or second year curriculum of a progressive medical school. The revision has been thorough and the information on plant constituents is, for the most part, of recent acquisition and an immense amount of new matter has been added, particularly in the field of the inorganic drugs. This is an especially desirable feature since heretofore it has been in this department that contemporaneous materia medica literature has been weakest.

Manuel Complet de Gynecologie Médicale et Chirurgicale. Par A. Lutaud. Professeur libre de Gynecologie, Medecin adjoint de Saint-Lazare, Membre fondateur de la Société Obstetricale et Gynecologique de Paris, etc. Nouvelle edition entièrement refondue contenant la technique opératoire complete, et 607 figures dans le texte. Paris: A. Maloine, Editeur, 1900.

The new edition of Lutaud's well-known work retains not only its reputation among French gynecological treatises, but compares well with the many text-books in our own and the German language. The subdivision of the matter is eminently practical; the anatomy, embryology and pathology of each part of the female sexual tract being considered in a separate chapter. The language throughout is clear and to the point and the descriptions, especially of the operative procedures, are concise and free from ballast. Of operations, only those which have universally found favor are considered in detail and the frequency with which American names are encountered is gratifying. The great stress laid upon asepsis, upon radiography and upon ureteral catheterization, speaks for the modern character of the book. The illustrations hardly come up to those of many of our own works, but those illustrating plastic operations on cervix and vagina are exceptionally good. The pathology, as in so many treatises on this branch of surgery, is deficient. The chapter on Ectopic Gestation is practical and well written. Several pages are devoted to the subject of Artificial Fecundation. On the whole, the book can be most warmly recommended to American students and physicians, the more so since the clearness of the style will not demand a very extensive knowledge of French.

A Manual of Otology. By Gorham Bacon, A.M., M.D., Professor of Otology in Cornell University Medical College, New York. Introduction by Clarence J. Blake, M.D., Professor of Otology in Harvard Medical School, Boston. Second Edition. Lea Brothers & Co., Philadelphia and New York.

The second edition of this manual, following so closely on the issue of the first and showing so many points of improvement in what was already a very acceptable and useful volume, has in it all the characteristics of a popular work to be read by the general practitioner when larger works would be neglected, much as Nettleship's "Diseases of the Eye" has displaced the larger books on the same subject. This volume, like the other popular book cited, is handy in size, excellent in type, attractive in presentation and form. The two new plates add a great deal to the value of the book, especially the first, showing the section of the temporal. The coloring of the drum-membranes in the second plate is far from being first-class, yet the plate illustrates.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, DECEMBER 22, 1900. NO. 25.

ORIGINAL ARTICLES.

A RAPID AND SIMPLE OPERATION FOR GALL-STONES FOUND BY EXPLORING THE ABDOMEN IN THE COURSE OF A LOWER ABDOMINAL OPERATION.

By HOWARD A. KELLY, M.D.,
OF BALTIMORE, MD.

I HAVE dwelt elsewhere (see MEDICAL NEWS, Dec. 16, 1899) upon the importance of utilizing an abdominal incision which is over 8 centimeters in length, for the purpose of investigating the condition of all the important viscera which are accessible to touch, provided the condition of the patient is satisfactory and there is no technical objection to the slight delay involved. I desire now to speak of a simple and satisfactory method of removing stones when found in the gall-bladder in this way.

When the incision is made in the lower part of the abdomen either in the median line, or as I have made it in one instance, over the site of the vermiform appendix, the hand is introduced into the abdomen hugging the abdominal wall, conducted up over the omentum and the colon as far as the liver where the gall-bladder is easily discovered in its notch on the right, as a somewhat tense or flaccid sac filling the fissure and projecting out a little beyond the hepatic border. It is my practice to squeeze the gall-bladder and note the rapid collapse showing that the cystic duct is pervious. If there is a stone present it is easily felt through the thin walls by palpating from the cystic duct up toward the fundus. In order to remove a stone, if the gall-bladder is much distended, it should first be emptied by compression between the thumb and two fingers; this allows the stone to be grasped or rather hooked up by the first and second fingers to the top of the gall-bladder, where the stone is then lifted firmly up against the abdominal wall which is thrust forward until a distinct eminence appears on the skin surface just below the margin of the ribs. Care must be taken not to allow any loop of intestine or the margin of the liver to intervene between the bladder and the abdominal wall.

An incision about 4 or 5 centimeters in length is now made with the free right hand, down through the abdominal parietes over the eminence directly upon the stone, cutting straight through layer by layer in a vertical direction. The pressure from within keeps the tissues anemic as skin, fat and muscle are successively divided. The white peritoneum is easily recognized, and on reaching this layer a little nick is made and the two edges caught with mosquito forceps; as the peritoneal incision is made a little larger, the gall-bladder with the stone appears in the incision, is opened and its edges caught as the incision is made large enough to evacuate its contents; the stone may then clear the opening suddenly and land on the floor some distance from the table. The edges of the gall-bladder, held up by four of Halsted's delicate mosquito forceps, are now united by a fine silk suture beginning at one end of the incision and continued to the other, embracing all the coats but the mucosa. The same suture is then continued back to the starting-point as a quilted suture, burying the first layer, when the ends are tied together. If the gall-bladder is normal I do not hesitate to drop it without a drain. If the walls are diseased I drop the gall-bladder after closing with interrupted sutures and insert a small drain provisionally. The abdominal wound is then closed and the operation completed within a few minutes of its commencement. There is no danger of contamination of the peritoneum with bile as the gall-bladder is drawn well up into the parietal incision and the peritoneal opening thereby closed.

One of the first cases in which I resorted to this mode of discovering and removing a gall-stone was under the following unusual circumstances: The patient was a man, about forty years of age, in the care of Dr. Yost of Glen Rock, Pa., to whom I am indebted for the opportunity of seeing and treating him. He had always been healthy until he was stricken with typhoid fever November 1, 1898. Previously both his wife and daughter had been severely ill with the same disease and he had nursed them himself and remained in almost constant attendance. In its onset and its course his attack was a typical one. For the first ten days the temperature in the morning was 101° F.; in the evening 102.5° F.; for the succeeding ten days the morning temperature was 102.5° F., the evening temperature 104° to 104.5° F.; after this there was a gradual defervescence for three weeks followed by a slight recrudescence for a week, when the evening temperature reached 103.5° F. He was free from fever at about the thirteenth week. The bowel symptoms were never severe, there were no bloody discharges and no tendency to constipation, but there was some abdominal pain and slight distention. There was never any jaundice during the entire course of the attack. During the latter part of February, 1899, he had a slight attack of colic about the umbilical and the right iliac regions with some tenderness, lasting three or four days. After this the convalescence progressed in a perfectly normal manner with a fair appetite, digestion and nutrition.

*Address delivered before the Southern Surgical and Gynecological Association, Atlanta, Ga., Nov. 15, 1900.

At three o'clock in the afternoon of March 20, 1889, he complained suddenly of a severe colicky pain in the umbilical and right iliac regions, which increased steadily in spite of warm application, hypodermic injections of morphine and enemata of hot water; the pain was associated with some retching, slight vomiting and a desire to defecate frequently without result, he passing neither fecal matter nor any of the water of which one gallon was injected. Dr. Yost then fearing perforation of the bowel telegraphed for the writer, who operated with the aid of Dr. Thos. R. Brown, at 9 P. M., March 21, 1899.

The appendix seemed to be the likeliest seat of the trouble, so the incision was made over the right iliac fossa; when the abdomen was opened it was found filled with thin, watery, somewhat sticky fluid of a dark color but with no odor. There were no evidences of suppuration, but the intestines, uniformly injected and lack-luster, showed a general peritonitis. The appendix was normal, save the general injection covering its surface. Inasmuch as the color of the fluid in the abdominal cavity suggested bile, the incision was enlarged, the right hand and forearm introduced and the liver palpated. No rent could be detected in the collapsed gall-bladder, but a single large stone was distinctly felt.

Proceeding then on the assumption that the gall-bladder was ruptured, the stone was caught between two fingers and pressed up against the abdominal wall by means of the hand inside the abdomen. Then with the other hand the overlying tissues were cut through until the gall-bladder was exposed, excised and its edges caught with artery forceps on either side, when suddenly a large, clear, shining biliary calculus popped out and fell on the floor, rolling toward a crowd of some seventeen spectators, friends of the family crowded into the little attic room to witness the operation.

The point of rupture could not be found, therefore the incision in the gall-bladder was sutured to the abdominal opening and the bladder drained with several pieces of narrow iodoform gauze. The lower incision was also drained, after thoroughly washing out the abdominal cavity, with washed-out iodoform gauze.

The convalescence was uneventful, the temperature never rose above 100° F., although the pulse continued high for several days after the operation. The stools were somewhat constipated, of a grey color and clay-like consistency for about five weeks, when they gradually assumed a normal color as the cystic fistula closed and the bile resumed its natural channel. The discharge of bile through the fistula was very free for eighteen days and then ceased quite abruptly. The drains were removed gradually, the last piece being taken out on the thirty-third day. The urine was dark colored for about four weeks when it gradually assumed a normal color. The patient had never previously passed any biliary calculi to his own knowledge.

The gall-stone was about 1.5 x 1 x 1 cm., purely translucent and entirely without any traces of pigment; the analysis showed that it consisted of pure cholesterin.

Fig. 1.

The left hand, covered with a glove, is introduced through the incision above the symphysis; the gall-bladder is found and the stone pushed up into the fundus and against the abdominal wall where it makes a decided prominence. The free hand is next engaged in liberating the stone by cutting directly down through the tissues of the wall until the bladder is opened and the stone escapes.

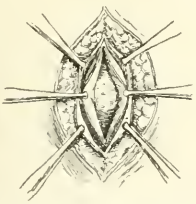
Cultures, made subsequently from the abdominal cavity and from the bile as it issued from the fistula and from the center of the stone in the hope that typhoid bacilli might be found, proved negative. A chemical examination of the fluid obtained from the abdominal cavity showed that it contained the biliary pigments and the glycocholate and taurocholate of soda. It was therefore certain that there was a rupture of the gall-bladder and that the severe abdominal symptoms had been produced by the peritonitis set up by the irritating biliary salts.

The patient came to my office ten months later, with his incisions perfectly healed and in excellent health.

In addition to the case just related, I have operated upon seven others, all women.

Case II. was a difficult hysteromyomectomy, performed April 1, 1899, on a married woman thirty-nine years of age. After checking all the hemorrhage in the pelvis, the right arm was introduced and the other abdominal viscera palpated. A large irregular stone was found in the gall-bladder; this was caught by two fingers and pushed up into the fundus against the abdominal

Fig. 2.



The incision in the abdominal wall, showing the deep fascia held up by four, and the incised gall-bladder held open by two pairs of mosquito forceps. The stone is seen in the middle ready for delivery.

wall. With a scalpel in the left hand the tissues were then divided in a vertical direction until the gall-bladder was exposed, when it was incised and its edges secured with forceps; the incision was then enlarged and the stone, which was black and about 4 x 3 cm. in diameter, was pushed out. The gall-bladder was drawn out of the wound to one side and surrounded by gauze until the opening was closed by mattress catgut sutures, the abdominal wound was then closed over the gall-bladder, after which the abdomen below was also closed without drainage. I saw this patient twenty months after the operation in greatly improved health without any complaints referable to the operation.

Case III. was a woman, thirty-two years of age, operated upon April 22, 1899, for a myomatous uterus from which two tumors were removed together with one left broad ligament myoma. The uterine incisions were all closed with catgut, after which the remaining abdominal organs were examined through the incision. The gall-bladder was found to contain two stones which were removed as in Cases I. and II. The incision in the gall-bladder was closed with interrupted catgut sutures, after which both abdominal incisions were closed without drainage. The recovery of the patient was uneventful.

Case IV., a patient of Dr. August Horn of Baltimore, was a married woman, sixty years of age, with a large multilocular cyst of the right ovary. After removing the cyst, in palpating the other organs the gall-bladder was found to contain stones. The abdomen was lax and the gall-bladder was drawn down near the upper end of the wound which extended almost to the umbilicus; after surrounding it with gauze it was cut open and the stones removed. The opening was then closed with two rows of mattress sutures of fine silk, easily applied in the thickened walls of the bladder. The abdomen was washed out and the wound closed without drainage. The stones were all dark in color, the largest one being 3 cm. in diameter.

The convalescence was uneventful and without pain; the highest temperature was 100.5° F. on the second day.

Case V. was a patient of Dr. Fry of Washington, operated upon May 23, 1900; the patient, forty-eight years of age, had a large ovarian cyst; after removal of the tumor, in palpating the other abdominal organs the gall-bladder was found choked with a mass of large stones; it was pushed up against the abdominal wall and opened by a longitudinal incision and 20 stones removed varying in diameter from 3½ to 1 cm. The gall-bladder was then sutured by interrupted fine silk sutures, and dropped back into the abdomen with a small iodoform-gauze drain. The abdominal wound from below was closed completely. There was no leakage at all from the gall-bladder, and upon removal of the drain upon the seventh day the opening closed without suppuration.

Case VI. was a woman, fifty-three years of age, a patient of Dr. J. A. Evans of Baltimore; was operated upon October 18, 1900, for a large myomatous uterus filling the lower abdomen. The uterus was removed by hysteromyomectomy from left to right; in order to get it out, it was necessary to make a long incision up to the umbilicus. After completing the pelvic operation and examining the other abdominal viscera, the gall-bladder was found shriveled, white and much thickened, and containing stones. The gall-bladder was drawn toward the upper end of the incision, its fundus incised and two large black stones removed. The walls of the gall-bladder were about ½ cm. in thickness and moderately vascular; the incision was closed by interrupted fine silk sutures. The median abdominal incision was closed up to the upper angle where a fine gauze drain was laid down to the gall-bladder. The patient made an excellent recovery, but with the discharge of a moderate amount of sticky fluid, evidently coming from the gall-bladder, which continued for several weeks.

Case VII. was a patient operated upon November 17, 1900, for a large myomatous uterine

body filling the lower abdomen; it was necessary in order to get it out to make an incision extending from the symphysis up to the umbilicus. After taking out the tumor and palpating the other abdominal viscera a stone was found in the gall-bladder. This was then removed by drawing down the liver and pulling up the long incision to the right side. After packing off the gall-bladder with gauze the incision was made and the stone extracted; the wound was then closed with silk sutures. No drain was used.

Case VIII. was a woman, forty-four years of age, upon whom I performed hysterectomy for a large fibroid uterus filling the lower half of the abdomen; it was necessary, in order to remove the mass, to extend the incision from the symphysis pubis up through the umbilicus and 8 centimeters beyond it. After completing the pelvic operation and examining the rest of the abdominal viscera, a long vermiform appendix was found buried in adhesions and concealed behind the colon, the right kidney was movable, and the transparent gall-bladder was seen full of stones from 1½ cm. in diameter and smaller. Dr. G. B. Miller, who completed the operation, opened the gall-bladder and removed 32 stones, closing it by two layers of fine silk sutures.

Dr. Peters finds, upon going over my anesthesia slips, that I have dictated notes as to the condition of the gall-bladder in 49 cases and stones have been found and removed in 8 per cent. of these.

I offer no apology for removing these foreign bodies by an operation so simple and so safe when the abdomen is once opened for some other more serious cause.

I need but to refer to the distressing sequelæ of a cholecystitis, or a cholangitis, once the stones give rise to an infection and afford by attrition of the mucosa the portal of entry in the surrounding tissues, or, on the other hand, to the miseries of a patient whose stone has begun to wander down toward the duodenum. A still more cogent reason is perhaps found in the frequency with which stones are associated with cancer of the gall-bladder.

In connection with my recommendation to remove gall-stones whenever they are discovered in this way the question of their relative frequency becomes a matter of considerable importance.

Naunyn (*Klinik der Cholelithiasis,* Leipzig, 1892) quotes the frequency of gall-stones from the pathological records of the following clinics:

Peters (Kiel)	5	per cent.
Rother (Munich)	6	" "
Fiedler (Dresden)	7	" "
Schloth (Erlangen)	7.2	" "
Roth (Basel) I.	9	" "
Roth (Basel) II.	10.9	" "
Frank (Vienna)	10	" "
Schroeder (Strassburg)	12	" "

Schroeder's material covering all ages shows that there is a remarkable increase in the percentage according to age.

Table I.

No.	Initials.	Physician.	Date of Oper.	Primary Operation.	Stones.	Gall-Bladder Operation.
1	S.	Dr. G. P. Yost.	Mch. 21, 1899.	Lateral incision over vermiform appendix.	One pure cholesterin.	Incision below the ribs. Gall-bladder sutured to abd. opening, drain. Recovery.
2	M. G.	Dr. E. S. Fruitt.	Apl. 1, 1899.	Median Incision. Hysteromyomectomy.	One large, rough, black stone.	Incision below the ribs. Gall-bladder drawn out of wound and surrounded by gauze. Closed by mattress catgut sutures. No drain. Recovery.
3	E. S.	Dr. D. B. Sprecher.	Apl. 22, 1899.	Median Incision. Myomatous uterus.	Two stones; one the size of a horse-chestnut.	Incision below the ribs. Gall-bladder closed with interrupted catgut sutures. Recovery.
4	B. B.	Dr. A. Horn.	Apl. 9, 1900.	Median Incision. Multilocular cyst of right ovary. Wound extended almost to umbilicus.	One large stone 3 cm. in diam. and several smaller ones. Dark in color.	Gall-bladder drawn down near upper end of median incision, isolated with gauze, opened. Closed with two rows of mattress silk sutures. No drain. Recovery.
5	L. H.	Dr. Henry D. Fry.	May 23, 1900.	Median Incision. Large ovarian cyst.	Twenty stones, 3½-1 cm. in diam.	Gall-bladder exposed by an infracostal longitudinal incision. Closed by interrupted silk sutures. Small iodoform gauze drain. No discharge. Recovery.
6	J. T.	Dr. J. A. Evans.	Oct. 18, 1900.	Median Incision. Large myomatous uterus. Hysteromyomectomy.	Two large black stones.	Gall-bladder drawn down into median incision and stones removed. Closed by interrupted silk sutures. Fine gauze drain to gall-bladder. Recovery, with discharge of some sticky fluid for several weeks.
7	M. S.	.....	Nov. 17, 1900.	Median Incision. Large myomatous uterus. Hysteromyomectomy.	One clear cholesterin stone.	Gall-bladder packed off with gauze and incised through large median abdominal incision. Gall-bladder completely closed with silk sutures.
8	R. C.	.....	Nov. 24, 1900.	Median Incision Large fibroid uterus. Hysterectomy.	Thirty-two small stones, 1½ cm. in diam. and smaller.	Gall-bladder drawn down into median opening and incised Closed by two layers of fine silk sutures. First, mattress; second, continuous.

Age.	Sections.	Cases with gall-stone.	Percentage of gall-stone cases.
0–20	82	2	2.4
21–30	188	6	3.2
31–40	209	24	11.5
41–50	252	28	11.1
51–60	161	16	9.9
60 and over.	258	25	25.2

Of these it is remarkable that 4.4 per cent. were in men and 20.6 per cent. in women, and it is stated that stones were found much more frequently in women who had borne children.

I am not aware that statistics of any considerable number of cases have ever been presented from this country. With the permission of my colleague, Professor Wm. H. Welch, I asked Dr. Clelia D. Mosher, assisting me in my private gynecological work, to review a thousand autopsies made in the Pathological Department of the Johns Hopkins Hospital to investigate this point. The results of Dr. Mosher's excellent labors demonstrated that biliary calculi were found in 59 cases or 5.9 per cent.; in 31 or 4.8 per cent. of the males and in 28 or 7.8 per cent. of the females.

SOME NOTES ON THE TREATMENT OF RHEUMATISM.[1]

By ALFRED STENGEL, M.D.,
OF PHILADELPHIA;
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

It is not my purpose to discuss elaborately either the nature of rheumatism or its treatment, but, in offering some suggestions based upon my own experience in the treatment of the disease, it is necessary to consider briefly the nature or pathology of the malady.

Acute articular rheumatism is in all probability an infectious disease, although the infective agent has not been positively determined. The older theories regarding the nature of rheumatism have proved inadequate in the light of modern research. It does not any longer suffice to say a disease is dependent upon a dyscrasic state; we recognize that the term dyscrasia is but a cloak of ignorance. If it be intended to imply a constitutional, inherited or acquired weakness of some sort that renders one person more liable to a disease than another, it may be true that rheumatism is favored by such a condition, but in this sense pneumonia is equally dependent upon a dyscrasia. If, again, dyscrasia comprehends a disorder of the blood or of the juices of the body, it remains to prove the existence of such a disorder and its chemical or vital character as contrasted with the existence in the circulating liquids of infective micro-organisms. The various hypotheses regarding the rôle of acids of one kind or another have been disposed of by chemical studies, although much remains to be learned of the metabolism of the disease. The nervous theory of rheumatism needs little or no discussion. Nervous disorders undoubtedly attend and follow the disease, but the causal relationship has been especially traced by those who have confounded rheumatoid arthritis and articular rheumatism.

The infective theory rests upon the peculiar symptoms, course and complications, and the discovery in the lesions of the latter of various micro-organisms. It has been further suggested by the association of rheumatism with certain local infective processes such as tonsillitis and suppurative foci of various localities. The specific organism has not, however, been isolated, or at least the claims to specific relationship have not been established for any one of the several bacteria that have been obtained from the local lesions, the blood, and the urine of cases of rheumatism. The majority of the bacteriologic studies agree in having discovered some form of micrococci, mostly staphylococci; and the same organisms are generally found upon the diseased valves in cases of rheumatic endocarditis. A peculiar bacillus has been isolated in some cases, and has been regarded as specific by some investigators.

It is the opinion of many that rheumatism is a form of infection closely allied to pyemia, but differing in the localization of the lesions and the virulence of the infection from other cases of pyemia. The suggestive resemblance of pyemic arthritis is of importance in this connection. Ordinarily, the latter variety of joint disease differs in clinical and pathologic characters from that which we call articular rheumatism; but a close analysis of series of cases leaves no doubt that there is a gradual merging of one group into the other so that it is impossible to establish a line of separation. The less virulent, polyarticular and cryptogenetic forms of arthritis are called rheumatism; the severe, often monarticular, and manifestly secondary, cases are put down as pyemic. In the same connection it must be confessed that no very definite distinctions can be traced between rheumatism and the rheumatoid conditions associated with such infections as scarlatina, gonorrhea, dysentery, etc. There is doubtless a difference in the etiologic cause in these different forms of disease, and there is correspondingly a difference in their nature, but the difficulty of differentiation must be recognized to appreciate that articular rheumatism as we now understand it is a clinical condition rather than an established pathologic entity. Just as in the case of pneumonia forms caused by different micro-organisms have a very close resemblance in their manifestations, so in rheumatism it is likely that a variety of micro-organisms of moderate virulence may operate to produce a similar pathologic result. The result in question is a serous or serofibrinous inflammation of the joints, the pleura, the endocardium, pericardium, etc., with as a rule moderate systemic infection or intoxication.

In considering the question of treatment it is important to recognize several fundamental facts. First, the tendency in many cases of rheumatism is toward spontaneous recovery. This may occur in a few days and after very mild symptoms, but sometimes only after a prolonged course. These facts should have been more thoroughly appreciated by those who advocated suggestion and other hypnotic measures of treatment. Second, complications, such as pleurisy, endocarditis, pericarditis, etc., are frequent and are more likely to occur in protracted cases than in those of short duration. Third, the complica-

[1] Read by title at the meeting of the Medical Society of Pennsylvania, September 19, 1900.

tions are probably as a rule secondary to the joint disease and not to the infective lesion (such as tonsillitis) that was the primary focus; consequently the severity of the local joint lesions bears a relation to the likelihood of the development of complications. I state these views as probable not as absolutely proved.

Of the drugs that have been used in the treatment of rheumatism, the derivatives of salicylic acid deservedly occupy the first place in professional estimation. Salicylic acid is not, as far as we know, a specific. In many cases it fails entirely; in a greater number it is beneficial in relieving pain and other symptoms, but fails to give complete relief; in some cases its action is so immediate and final that the term specific seems almost justified. How much this difference in action of the drug depends upon etiologic differences in particular cases is unknown. The possibility of such an explanation of the failure or success of the treatment cannot, however, be denied. I am reminded of an experience in a case of rheumatic pleurisy in which the fluid in the chest disappeared with remarkable rapidity after the administration of salicylate of soda, and of other less striking but suggestive results under similar circumstances. The efficiency of the drug in rheumatic pleural effusions has been too frequently observed to permit the belief that the results have been mere coincidents; and the rapidity and thoroughness of action indicate a relationship of the drug to the disease or some cases of the disease that warrants a place near to the remedies we term specifics. One is reminded of the action of potassium iodide in actinomycosis or of arsenic in leukemia and pernicious anemia.

If, however, the salicylic-acid preparations are not specific they at least relieve pain and suffering in a majority of cases, and thereby benefit the patient's general condition. This is doubtless advantageous to the end of helping the combat on the side of the systemic resistance to the infection. Of the preparations of salicylic acid I shall say little, but wish to refer especially to the external applications of one form, the salicylate of methyl or oil of wintergreen. The sodium salt is probably most frequently employed for internal use, and, excepting in rare instances when some other form is more acceptable to the stomach, proves satisfactory if the internal administration of salicylates is likely to be beneficial in any form. The Germans advise large doses, and, though these may cause toxic symptoms, I have found them more satisfactory than small doses spread over a longer time. If salicylic acid is likely to prove useful it will do so in a comparatively short time. The administration of a dose of ten grains of the sodium salt three times daily does not suffice. When this plan has been used the drug has relieved pain scarcely at all and has had no appreciable effect on the course of the disease. From 100 to 150 grains should be given in twenty-four hours for two or three days if symptoms of salicylism have not appeared; after that period the dose may be reduced one-half and after one week's treatment the drug may often be discontinued. Persistent use of the remedy undoubtedly causes depression and other complications. The same general principles apply to the internal use of oil of gaultheria, salicin, ammonium and strontium salicylate, etc.

The simultaneous or separate use of salicylate of methyl, applied to the skin in the form of a ten-per-cent. or twenty-per-cent. ointment and covered with lint and oiled silk, is extremely satisfactory. I have repeatedly tested the pain-allaying power of such local treatment comparing it with simultaneous applications of lead-water and laudanum, Fuller's lotion and the like. Invariably the ointment has given the greater relief and the systemic action of the drug was undoubtedly exercised, as abundance of salicyluric acid in the urine indicated the absorption of the drug.

The relief of pain secured by the internal and external use of salicylates is beneficial in several ways, the chief of which is that such freedom from pain causes rest of the diseased parts by relaxing muscular spasm and at the same time improves the general condition of the patient. Some rest may, however, be obtained in another and better way, *viz.*, by the use of splints or plaster casts. For several years past I have treated cases of acute rheumatism in this way. My first experiences were with cases of gonorrheal rheumatism, but more recently I have practised plaster-fixation in cases of ordinary polyarticular rheumatism. The plaster cast almost invariably relieves pain by reducing the muscular spasm and securing immobility and its application is generally followed by rapid subsidence of the local signs of inflammation. The process of applying the cast has never been so painful to the patient that it had to be abandoned. There has never been any increase of swelling after the cast was applied and it has not, therefore, been necessary in any case to remove the cast on account of pressure. On the contrary, it has often happened that a new cast was needed in two or three days on account of the reduction in the size of the joint. In very acute inflammatory cases I have in the beginning covered the joint with lint on which salicylate of methyl ointment was spread and have then fixed the part with a light cast, removing this in twenty-four or forty-eight hours. The ointment may cause irritation if it is allowed to remain too long in close apposition with the skin. In a few instances of rather subacute character it has proved useful to cut the cast so that daily dressings might be applied to the joint. In none of my cases has it been necessary to continue fixation so long that there has been any danger of ankylosis. As soon as the inflammation has measureably subsided it is advisable to discontinue the cast and in but few instances has the condition relapsed so as to require reapplication of the plaster dress-

ing. Occasionally I have allowed the cast to remain for considerable periods, removing it from time to time to examine the joint or practise gentle manipulations.

My experience with this treatment has been confined to gonorrheal rheumatism and polyarticular rheumatism. In the former affection it has long been used by the profession and little need be said at this time. In one very marked case which I saw in consultation with Dr. L. M. Allen, a cast was applied by the attending physician when I had so little hope of its usefulness that I had advised other treatment. The beneficial effects of the fixation were immediate and marked and the patient recovered completely in a surprisingly short time. When I saw him the disorganization of the joint and the involvement of surrounding tissues appeared so great that it seemed wiser to trust to local counterirritation and general internal treatment. The fortunate result, however, disproved this opinion. In other cases of gonorrheal rheumatism equally satisfactory results have been reached, though less promptly.

In polyarticular rheumatism the fixation method has been most useful when the knee, elbow, and ankles have been the affected joints. The wrists and smaller joints can be managed with splints and in other ways quite as satisfactorily and with less trouble. In one case of a relapsing character, both before and after fixation, the cast had little apparent effect in the direction of reducing the duration of the disease, though it undoubtedly relieved pain. In all of the others the duration of the disease was seemingly reduced.

It is well recognized that some cases of polyarticular rheumatism prove stubborn and do not yield to treatment with salicylic acid combined with rest. In the same cases the general condition of the patient is often unsatisfactory and it is advised to discontinue salicylates and to resort to general tonics. This advice is undoubtedly based upon sound principles, inasmuch as the cure of the disease depends upon the general vitality rather than upon the use of any special remedy. In a number of cases of this sort I have employed bichloride of mercury in small doses with good effect, and have been led to attribute the result to a tonic influence of the drug, as I have in cases of secondary anemia of various sorts found this remedy undoubtedly efficacious when administered continuously for long periods of time in doses of from grain 1/96 to grain 1/72. The remedy seems to be of value as a tonic or stimulant of hemogenesis and not as an antiseptic. As far as its application in rheumatism is concerned, I have found it useful only in subacute cases with little local inflammation and with general systemic depression. Other tonics may be valuable, but none of them has seemed to be of especial use in my experience. Sometimes the general condition of the patient has been favorably influenced by the administration of iron, strychnine, and cod-liver oil, but none of these has seemed to exercise the beneficial effect that has followed the use of bichloride of mercury. The iodides are of undoubted value in the more chronic cases; but I have little experience, and none favorable, of their use in subacute cases.

I do not mention the older alkaline treatment, because I have not found it of value.

Finally, I wish to refer to serum treatment. A number of investigations of the value of serum from convalescents have been published, but thus far no useful results have been obtained. It has occurred to me that an antistaphylococcus serum might be useful if staphylococci play the part in etiology that many believe. A difficulty in the way of following out this thought is the unreliability of the preparations that have thus far been made. My own attempts at obtaining an antistaphylococcus serum have been futile, and I therefore made a few trials of antistreptococcus serum, in the hope that its general antibacterial properties (as contrasted with the specific antistreptococcic action) might prove useful in rheumatism. The three cases in which I employed this preparation were instances of obstinate rheumatism that had not yielded to other treatment. In each of them improvement soon followed the injections. The dose of serum injected was one-third of the customary dose used in streptococcus infection, and the remedy was administered every other day for a period of a week or more, when ordinary treatment was resumed. It would be rash to draw conclusions from so limited an experience, but as far as my trials went there was every encouragement to continue the treatment in suitable cases.

REPORT OF TWO CASES OF SPORADIC OR FAMILY TRICHINOSIS; WITH REMARKS ON THE IMPORTANCE OF EOSINOPHILIA IN THE PERIPHERAL CIRCULATION AS AN AID TO DIAGNOSIS.[1]

By HERMON C. GORDINIER, M.D.,
OF TROY, N. Y.

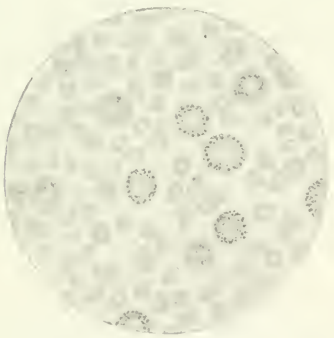
Although trichinæ have often been observed since their recognition by Sir James Paget and Owen in 1835 in the muscles, either in their encysted or larval state, they were considered as pathological curiosities to be found at the autopsy-table only. It remained for Prof. Zenker, the eminent pathologist of Erlangen, then of Dresden, to associate for the first time the clinical symptoms of a grave and fatal case with the presence in the muscles and alimentary canal of numerous living trichinæ.

His case, in abstract, was as follows: A girl, aged twenty years, was admitted to the General Hospital of Dresden on January 12, 1860. She had been ill since Christmas and at the beginning of the New Year had to go to bed. She com-

[1] Read at the annual meeting of the New York State Medical Association, 1900.

plained of lassitude, insomnia, anorexia, constipation, thirst and fever. The fever at the onset was quite high, the abdomen was considerably distended and tender. The spleen was not palpable and rose-spots were absent. The diagnosis of typhoid fever, however, was made. Very soon there occurred much pain in the muscles, especially those of the extremities, which continued day and night. The arms and legs were flexed and could not be extended without the production of great pain. Edema of the legs was present. The patient developed shortly after a pneumonia of a typhoid type, from which she succumbed on January 27th. The postmortem being held the next day, Prof. Zenker was greatly surprised to find, in the first sections of muscles examined microscopically, numerous non-encapsulated trichinæ in and between the muscle fibers. A more thorough search showed the muscles to be literally swarming with trichinæ. Peyer's patches were found normal. Prof. Zenker also found living adult

Fig. 1.



Eosinophilia in Trichinosis.

trichinæ in the intestines, and was able to find trichinæ in the flesh of the animal, some of which had been eaten by this unfortunate girl. As numerous individuals had partaken of the flesh of this same carcass several cases of trichinosis were treated by him. This important contribution to medicine of the discovery of a severe and fatal case of trichinosis was heralded throughout the world and soon much confirmatory evidence was forthcoming of its great value. Since then over a hundred epidemics of trichinosis have been recorded from North Germany alone, with similar records from this and other countries.

The fact that sporadic cases of trichinosis are commonly overlooked is well illustrated by the remarks of Prof. Osler in his article on the clinical features of this disease, in which he says: "Until quite recently I have had no clinical experience with this disease, having seen to recognize but one case in Traube's clinic in Berlin in 1873. The probability is, of course, that in a hospital service of more than twenty years I have frequently overlooked cases just as might have been done in three or four of the cases here reported." These remarks of Prof. Osler may, I believe, with propriety, be applied to most of us. We doubtless have seen, in times past, cases of sporadic or family trichinosis which we have diagnosed and treated as cases of rheumatism, *la grippe* or typhoid fever; trichinosis bearing more than a superficial resemblance to all these diseases.

Owing to the careful observations of Dr. Thomas R. Brown, of Johns Hopkins Hospital, who declares that in trichinosis there is an enormous increase of the eosinophiles in the blood, we now possess a very simple means of diagnosis which will enable us in most if not all instances to recognize this hitherto obscure disease. Dr. Brown's first contribution on this subject was published in the *Bulletin of the Johns Hopkins Hospital*, April, 1897, entitled "Studies in Trichinosis." Here he reports his observation of the condition of the blood in his first case of trichinosis. He found a gradual rise in the proportion of eosinophiles, reaching 68.2 per cent., 35 per cent. higher than any previous record, and from this point a gradual decline to 16.8 per cent. on the patient's discharge. There was a coincident depression of the polymorphonuclear neutrophiles, reaching one time 6.6 per cent., while for two weeks these forms showed an absolute decrease in the blood, notwithstanding the marked leucocytosis reaching on some occasions about 30,000 per cubic millimeter. Dr. Brown's second contribution to this subject appeared in the *Journal for Experimental Medicine*, Vol. III., No. 3, 1898, entitled "Studies in Trichinosis with Especial Reference to the Increase of Eosinophiles in the Blood and Muscles, the Origin of These Cells and Their Diagnostic Importance." Here he reports, in full, his first case together with two new ones, and from the study of the blood draws the following conclusions: (1) That there is a marked increase in the percentage of eosinophilic cells in the blood in trichinosis. (2) That this increase may be used as a diagnostic sign in this disease. (3) That this disease in its sporadic form is more common than has hitherto been supposed, as shown by the discovery of the three cases above described within a comparatively short time at the Johns Hopkins Hospital. (4) That a systematic examination of the blood should be undertaken in cases with indefinite intestinal, muscular, or articular symptoms, in hope that in some, at least, of the hitherto doubtful cases a diagnosis may be reached.

The discovery by Dr. Brown of the presence in trichinosis of an eosinophilia of a higher grade than any other known condition is one of the most valuable contributions to medical science, being second only in importance to that of Zenker. The observations of Brown have been recently verified by Cabot, Gwyn, Atkinson, Stump, Blumer and Newman. In Cabot's case a differential count of the leucocytes showed 27

per cent. of eosinophiles. In the case of Gwyn the percentage of eosinophiles was between 33 per cent. and 66 per cent. In Atkinson's case it reached 8 per cent. and in the case of Stump 52 per cent. of eosinophiles were found. In each of the nine cases reported by Drs. Blumer and Newman, the highest percentage of eosinophiles was, respectively, 40.6 per cent., 41.5 per cent., 36 per cent., 33 per cent., 33.6 per cent., 46 per cent., 39.4 per cent., 50.4 per cent. and 20 per cent.

The histories of my own cases are as follows:

Case I.—Sidney V., thirteen years of age, entered the Sanitarium Hospital November 8, 1899. His family and personal history is of no especial interest in relation to his present condition. This began about November 1, 1899, when he noticed that his face was swollen and that he had pains in his eyeballs. He became breathless on exertion and his feet felt heavy and swollen. He was feverish and chilly and had lost all desire for food. Could elicit no history of any gastro-intestinal disturbance. He stated he had eaten, during the past six months, quantities of "blutwurst" and that his father and brother had also eaten the same and that they had suffered with pains and soreness of muscles of arms and legs.

Present condition.—Patient's height, five feet; weight, 100 pounds. He appears very anemic. The face, especially about upper and lower eyelids and over malar prominences, distinctly swollen. Tongue heavily coated, mucous surfaces pale, no stiffness or tenderness of tongue. Larynx not at all tender on manipulation. Slight tenderness of bodies of biceps and calf muscles. Muscular movements were not attended by soreness. Nerve-trunks not tender. No tenderness of bones or joints. Slight puffiness over tibia. Heart's apex in normal position, sounds normal, no adventitious sounds. Lungs negative. Liver dulness normal. Spleen not enlarged. Abdomen not tympanitic or tender. No rose-spots. On part of the nervous system nothing was found abnormal save slight diminution of the patellar tendon reflexes. Pulse regular, full rate 110. Temperature 102° F. Urine (twenty-four-hour specimen) light amber; sp. gr. 1008; alkaline in reaction; 480 grs. of urea per twenty-four hours; no albumin, sugar, casts, blood or pus. Diazo-reaction distinct.

Before entering the hospital the patient had been treated at another institution where the diagnosis of heart-disease with dropsy was made. My attention was directed to the patient through the courtesy of my colleague, Dr. James P. Marsh, in whose service he was, and who had made no diagnosis, but recognized the fact that he had never before seen a similar case. The peculiar location of the swelling about the face and especially the eyelids; the slight muscle tenderness; the entire absence of signs of disease in any of the organs, together with the history of having eaten, over a long period, "blutwurst," consisting as it does of coagulated blood with small chunks of pork, brought to mind at once the fact that we probably had to deal with a case of sporadic or family trichinosis. I suggested an immediate microscopic examination of the blood, which was carried out by Dr. E. W. Becker, the house physician. He found an enormous increase of eosinophiles, these being easily recognized at a glance beneath the microscope, in freshly-drawn blood. A careful differential count was then made of 1000 leucocytes after having been stained with Ehrlich's triacid mixture with the following result: Eosinophiles, 773; small lymphocytes, 124; large lymphocytes and transitionals, 49; polymorphonuclear leucocytes, 54; hemoglobin, 65 per cent. This was truly an enormous increase of the eosinophiles, there being 77 per cent. together with a remarkable decrease of the polymorphonuclear leucocytes. For the purpose of confirming the diagnosis, Dr. E. D. Ferguson removed some muscular tissue from the biceps of the left arm and right gastrocnemius muscles. The tissue was examined in the fresh state, after having been teased, without finding trichinæ. Their workings were evident, however, as several granular areas were seen together with longitudinal and transverse splitting of the muscle fibers. The remainder of the muscle tissue was sectioned after hardening in absolute alcohol and imbedded in celloidin. It was stained with hematoxylin and eosin. In several sections non-encapsulated trichinæ were found lying coiled up in characteristic granular areas of myositis. Many muscle fibers were found split both transversely and longitudinally. The connective tissue between the primitive muscle bundles was slightly increased. All these changes were marked only in close proximity to the position of the areas of granular degeneration. Differential blood-count November 28, 1899: Eosinophiles, 52.6 per cent.; polynuclear leucocytes, 36.6 per cent.; large mononuclear leucocytes, 1.9 per cent.; small mononuclear leucocytes, 7.7 per cent.

Case II.—W. W., forty-two years old, the father of the former case, came into the Sanitarium Hospital November 14, 1900. He was a painter by occupation. Never had been ill since childhood save eight years ago when he had an attack of painter's colic. Since early spring in common with his son, he has been eating large quantities of "blutwurst." Three months ago he was taken ill with chills, fever, cramps in stomach, severe headache and pains and aches all over the body. He consulted a physician who told him that he had malarial fever and treated him for several days. In a short time diarrhea supervened and has continued ever since. The pains and soreness in the muscles of the arms and legs have remained until the present time, although much less in intensity than at first. He complains of the muscles being tender, especially those of arms and the hamstrings of legs. These muscles frequently cramp, after which the arms and legs feel numb. The patient was a moder-

ately well-nourished man, 5 feet 6 inches in height and weighed 150 pounds, and walked unassisted to the hospital. His face was slightly swollen about the malar eminences, but no edema about eyes existed. His tongue was coated and his breath very foul. He was pale but much less so than his son. There was no swelling of the legs. The biceps, hamstrings, and calf muscles were quite tender, especially at the junction of the tendons with the bodies of the muscles. No nerve tenderness existed. No evidence of wrist drop. Reflexes normal. Movements of joints unattended with pain. When patient first became indisposed muscular movement created great pain. Examination of the thoracic and abdominal organs elicited nothing abnormal. Urinary examination negative. No diazo-reaction. Pulse 126, regular, full and strong. Temperature 99.6° F.

Examination of freshly-drawn blood showed a marked eosinophilia which evidently was not so great as in the first case. Differential count of 500 leucocytes gave the following result: Polymorphonuclear, 49 per cent.; small mononuclear, 18 per cent.; large mononuclear, 1.8 per cent.; and eosinophiles, 31.9 per cent. November 22, 1899, Dr. Ferguson excised a small portion of the right biceps muscle. Sections of this were examined in the usual manner, but without trichinæ being discovered, although a few granular areas of myositis were found.

Case I. is very interesting because of the entire absence of gastro-intestinal symptoms, such as vomiting, colic or diarrhea, and of great muscular pains. The only severe pains from which he suffered were those provoked by movements of the eyeballs. But one characteristic objective symptom was present, namely, swelling of the face and about eyes and over region of tibiæ. The case certainly was atypical and its true nature was only disclosed by a study of the blood which showed an enormous eosinophilia with a corresponding reduction of the polymorphonuclear neutrophiles. This led to the excision of the muscles with, as a reward, the finding of numerous non-encapsulated trichinæ, together with the pathological changes in the muscles excited by their presence.

The clinical history of Case II. was typical of a distinctly mild attack of trichinosis. The recurring chills, the fever, cramps in the stomach with diarrhea followed by severe headache and pains and aches all over the body, with soreness and tenderness of the muscles, all pointed to trichinosis. All of these symptoms, however, could have been easily counterfeited by those of *la grippe*, typhoid fever, or by an erratic type of rheumatism, and this error could have been more easily committed, owing to the general appearance of the patient and from the fact that he did not appear ill and was able to walk round the ward during his short stay in the hospital. But here, again, the blood-examination cleared up all doubt by showing a decided increase of eosinophiles. Although we were unable to find the trichinæ in the muscles, a few sections showed the characteristic changes incident to their presence.

These two cases, then, illustrate very clearly the great assistance rendered by a careful examination of the blood in establishing the diagnosis of trichinosis and are entirely confirmatory of the results of Dr. Brown's painstaking study of the condition of the blood in the peripheral circulation in this disease.

Since the publication or Dr. Brown's original articles, eighteen additional cases of trichinosis have been recorded, making with the two herein reported twenty in all. In nineteen of this number the presumptive diagnosis of trichinosis was made from the presence of marked eosinophilia alone, which diagnosis was subsequently confirmed in all save a few cases by actually finding trichinæ together with their pathological changes incident to their presence in the muscular tissue removed from the patients. In a fatal case reported by Dr. Howard of Cleveland a single examination of the blood disclosed the presence of no eosinophiles, although eosinophiles were found in the muscular tissue after death. It is possible in this case that repeated examinations of the blood might have shown an eosinophilia. It is also possible that in fatal cases of trichinosis shortly before death, a marked diminution or entire absence of eosinophilia in the peripheral circulation occurs. Although eosinophilia occurs in several diseases, notably leukemia, asthma, chronic eczema, pemphigus, prurigo, psoriasis and in individuals affected with some forms of intestinal parasites; it does not occur in any disease the symptoms of which resemble trichinosis. It is therefore very important that a systematic blood-examination be made in all doubtful cases.

THE SURGERY OF THE GASSERIAN GANGLION.[1]

By WALLACE NEFF, A.M., M.D.,

OF WASHINGTON, D. C.;

FORMERLY ADJUNCT PROFESSOR OF CLINICAL SURGERY AND SURGICAL PATHOLOGY, MEDICAL COLLEGE OF OHIO (UNIVERSITY OF CINCINNATI); LATE MAJOR AND BRIGADE SURGEON, U. S. V.; MEMBER SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

THERE is no more painful and distressing malady than trigeminal neuralgia, nor a more difficult and dangerous operation in surgery than extirpation of the Gasserian ganglion, which has been so successfully performed for its relief.

[1] Read before the Southern Surgical and Gynecological Association, Atlanta, Ga., November 15, 1900.

Neuralgia of the fifth nerve, variously described as trifacial, trigeminal, tic douloureux, prosopalgia, etc., is more frequent than all other forms of neuralgia, and has been recognized and treated in a variety of ways for centuries.

The *Lancet* (1829, p. 367) gives an interesting account of the discovery of notes and memoranda which were presented by Lord King to Dr. Clarke, at the College of Physicians, London, June 1, 1829, showing that John Locke was a physician, as well as a philosopher. The notes referred to his diagnosis and treatment of the case of the wife of the English Ambassador at Paris in December, 1677. He described with great accuracy the symptoms of tic douloureux, with reflections as to its cause, and the best method of treating it.

Neurotomy, for relief of facial neuralgia, is not a modern operation. It was first suggested by Albinus and Galen, and it was employed by Marechal, surgeon to Louis XIV., as early as the middle of the eighteenth century.

In 1798 John Haighton published an account of a successful operation for neuralgia of the face by section of the affected (infra-orbital) nerve. The operation was so frequently employed after this that it fell into disrepute. It was revived again about 1852 by Roux and others (Treves' Manual of Operative Surgery). Nerve-stretching succeeded neurotomy, and later neurectomy came into vogue. Horsley (*Brit. Med. Jour.*, Nov., 1891) mentions another method, the thrusting of a red hot wire into the foramen of exit, but this never came into general use. Nussbaum introduced ligation of the internal carotid, but this was soon abandoned.

In 1858 Carnochan of New York advised the removal of Meckel's ganglion, and the trunk of the nerve at its exit from the foramen. He reached the ganglion through the antrum. There have been many modifications of this operation, but they are all practically Carnochan's method. Leucke of Strassburg removed Meckel's ganglion by resecting the zygomatic arch, and turning it upward with the fascia attached, and thus reached the pterygoid fossa and resected the nerve and ganglion. Great deformity was the result, so Lossen of Heidelberg turned the flap downward instead of upward.

Horsley elevated the eye from the floor of the orbit, opened the infra-orbital canal, and followed the course of the nerve until he could divide it at its exit from the foramen rotundum. In 1872 Pancoast resected the inferior division of the nerve at its exit from the foramen ovale. Kroenlein resected the inferior and middle branches of the nerves as they emerged from the skull. The operations from the outside of the skull proving unsatisfactory, J. Ewing Mears (*Trans. Am. Surg. Assoc.*, 1884) proposed an intracranial operation, and removal of the Gasserian ganglion. Rose of London (*Lancet*, Nov. 1, 1890) made the first extirpation of the Gasserian ganglion on April 2, 1890. About the same time Andrews of Chicago made the operation also. Rose being the first to publish his results, the operation became known by his name. They both reached the ganglion by trephining the base of the skull in the pterygoid fossa, in front and at the outer side of the foramen ovale. The zygomatic arch was resected and turned upward, the coronoid process was divided and turned forward with the temporal muscle.

The Hartley-Krause method succeeded this and was described about the same time by Hartley in New York, and Krause in Germany. The time and method of both operators was so nearly identical that it has received the name of both. Hartley's first operation was made August 15, 1891 (*N. Y. Med. Jour.*, March 19, 1892) and Krause's February 23, 1892 (Die Neuralgie des Trigeminus). The operation consists in raising an omega-shaped osteoplastic flap from the temporal fossa. The only difference in the two methods being that Hartley used a chisel to raise the flap, and Krause an electric saw. The Hartley-Krause method, with or without modifications, is the one now employed by most operators.

To the brilliant operations and able writings of Tiffany,[1] Keen,[2] Spiller,[3] Carson,[4] Abbe,[5] Murphy,[6] Cushing,[7] Dana,[8] and Beck,[9] we owe in a large measure our present knowledge of this disease, and the best methods devised for its relief; and to them the writer is chiefly indebted for the information contained in this paper.

Anatomy.—In order to properly appreciate this affection, and the hazardous nature of the surgical intervention necessary to effect a cure, it might be well to briefly consider the anatomy of the region involved. The fifth nerve emerges from the brain with two roots. The posterior root, consisting of about a hundred bundles of nerve fibers and stronger than the other, is first visible in the groove of the crus cerebelli ad pontem. Its fibers are sensory. The anterior root is thinner, and covered by the posterior. It emerges from the gray nucleus of the fourth ventricle, and is first visible coming from the front portion of the pons Varolii. Its fibers are motor. These two nerves join, and, perforating the dura mater, their course leads toward a shallow depression in the petrous portion of the temporal bone called Meckel's cave. There the posterior sensitive root develops into a ganglion. Its fibers spread and ganglionary cells develop into a flat, oblong body, known as the Gasserian ganglion. Motor fibers have no part in this formation. From the convex border of the ganglion three nerves emerge, the ophthalmic, superior maxillary and inferior maxillary. There are very important structures in the immediate vicinity, the internal carotid, middle meningeal, and cavernous sinus.

The nerves leave the cranial cavity by different openings, the supra-orbital fissure, and the foramina rotundum and ovale, where the third branch is joined by the motor fibers of the anterior root. The object of the surgeon is to remove the sensory portion of the nerve and to leave the motor. This is very difficult, as they are close together, and deeply situated.

Etiology.—Victor Horsley gives as the causes of trigeminal neuralgia (1) cold; (2) worry and overwork; (3) alcohol; (4) ostitis of the alveolar borders of the jaws due to dental caries; (5) rhinitis; (6) traumatism. Authorities differ as to whether the disease is of central, or peripheral origin, but the consensus of opinion is that it is peripheral. It occurs in the majority of cases about middle life, or later, and is due to degenerative change in the nerve and its ganglion, and probably in the blood-vessels supplying it. It attacks women twice as often as men. It seldom attacks men under forty, and is three or four times more frequent in women than men under forty. Heredity is of little importance. In about one-fourth of the cases there is a history of migraine, but the most common exciting causes are cold, worry and overwork. The disease begins as a trigeminal neuritis, with herpes, associated often with disease of the gums and teeth. In a great majority of the cases, it is the second or third branch that is involved. It rarely begins in the ophthalmic, or remains localized in that branch, while it often affects the second and third branches for a long time. Dana (*Jour. Am. Med. Assoc.,* May 5, 1900, p. 1100) divides the disease into two types: (1) The migrainous type of early life. A disorder of the central sensory neuron, which may later develop into a true degenerative neuralgia. (2) The more common form, occurring after forty. A true infective neuritis, due to some local disease of the gums, or osseous tissues.

Pathology. — The following degenerative changes were found on microscopical examination by W. G. Spiller in two cases operated on by Cushing and illustrate the pathological condition that usually exists (*Jour. Am. Med. Assoc.,* May 5, 1900, p. 1094): (1) Tumefaction of the medullary sheaths, and axis cylinder, in certain bundles only, in all three divisions of the ganglion. (2) Tumefaction of the axis cylinder in a portion of the sensory root. (3) Numerous spaces in a portion of the sensory root, possibly resulting in part from degeneration of nerve fibers. The sensory root was not normal and a return of the pain was possible. (4) Intense degeneration in the center and peripheral end of the ganglion, and its peripheral divisions.

The blood-vessels were not distinctly diseased, and there was no evidence that the condition of the nerve fibers was due to vascular degeneration. The nerve-cells offered no evidence of the cellular origin of tic douloureux.

Diagnosis.—The fearful and distinctly localized pain renders the diagnosis easy, for as Trousseau (*Clinical Medicine*) describes it, "An individual, who but a moment ago was perfectly free from pain, is suddenly seized with horrible pain while talking. He puts his hands to his face and presses it with considerable force, sometimes rubbing it so much and so often that the hair on that side falls off. He goes on rocking himself, holding his head between his hands and uttering half-suppressed groans. This lasts for ten or fifteen seconds, one minute at most, and all is over without convulsions." The pain is so excruciating that the victims of it will readily consent to any operation, and are heedless of its danger, preferring death, often contemplating, and sometimes committing suicide to escape it. A patient of Murphy's expressed it most forcibly when he said, when told of the risks of an operation, "Anything you can get out of this better than death is clear profit."

Treatment.

Medical.—No permanent good has ever been accomplished by narcotic drugs. In the early stages of the disease, during the first or second year, heroic doses of strychnine often arrest and control it. In cases that have existed over six or seven years, a remission may occur, but no lasting benefit is obtained. Electricity sometimes palliates, but seldom cures.

Surgical.—A variety of operations have been devised, developing gradually from the simplest to the most intricate and dangerous. (1) The nerves were cut (neurotomy). (2) Portions were excised (neurectomy). (3) They were pulled and twisted out of their bony canals (neurexeresis). (4) Nerves were divided close to their central origin. (5) Extirpation of the Gasserian ganglion.

Simple section of the nerve gives immediate and magical relief, but the result is temporary, owing to the reunion of the nerve-channels by reparative action. If the lesion is central, a superficial operation is useless. If it is peripheral, it is necessary to remove enough to prevent bridging of the gap. The value of resection, therefore, depends upon the amount of nerve removed. Unless the duration of the disease is such that there is little doubt that the ganglion is involved, a peripheral operation should always first be made. If, however, there is recurrence of the pain after one or more peripheral operations, the more radical operation of removal of the Gasserian ganglion is necessary to effect a cure.

Tiffany (*Trans. Am. Surg. Assoc.,* Vol. XIV., 1896) offers the following suggestions for deciding when an intracranial operation should be made: "(1) *Intracranial operation to be thought of* (*a*) If more than one branch is affected. (*b*) If the painful area receives filaments from the branches near their exit from the head, *e. g.,* tongue, temporal region. (*c*) If the pain is not the expression of constitutional disease. (*d*) If a cause central to the ganglion does not exist. (*e*) If other measures have failed to relieve. (2) The intracranial operation that should be done, is removal of the lower two-thirds of the Gasserian ganglion with the second and third branches, as far as the foramina of exit from the skull, all in one piece, so as to be certain of the amount of tissue taken away. (3) The upper third of the ganglion and first branch may for the present not be excised for neuralgia."

Three routes have been followed in making this operation.

1. *Transmaxillary route* (Rose); removal of the superior maxillary bone. A dangerous method, as the cranial cavity is left in contact with the mouth, and infection is most likely to follow. There is much deformity, and this route has been practically abandoned.

2. *Pterygoid route* (Rose and Andrews); exposure of the foramen ovale by temporary resection of the zygomatic arch and coronoid process of the inferior maxillary. This route is difficult and dangerous, although not opening into the cavity of the mouth. The wound leaves much disfigurement. There may be necrosis of the zygoma, and the coronoid process may be lost. There is often severe hemorrhage from the internal maxillary artery, and the pterygoid plexus of veins. It is difficult to find the foramen ovale, the opening being sometimes hidden by the pterygoid spinous ridge. In trephining, the Eustachian tube may be opened and septic infection result. The dura mater may be opened, and the internal carotid may be damaged. The ganglion cannot be clearly exposed, and frequently only fragments are removed.

3. *Temporal route* (Hartley-Krause); this is the best route and the one followed by most operators with or without modifications. The advantages are a short incision, with little division of the muscle, and a cicatrix which is hidden by the scalp. The ganglion can be exposed with slight risk of opening the subarachnoid space. The squamous portion of the temporal bone is the only portion of the skull divided. There is no danger of communicating with the Eustachian tube and pharynx.

The principal difficulty and greatest danger is due to hemorrhage. The middle meningeal artery is often lacerated, necessitating much delay in reaching the seat of operation, frequently requiring packing, and a postponement of the operation. In order to reach the ganglion, it is necessary to elevate the brain and dura, so that it is often impossible to preserve the artery at the foramen spinosum. Krause advocates the double ligation of the vessel after it emerges from this foramen. This is difficult and often unsuccessful. The high temporal route is attended by many difficulties, which have been obviated to a great extent by Cushing's (*Jour. Am. Med. Assoc.*, April 28, 1900, p. 1038) modification of the Hartley-Krause operation, from which it differs only in detail. He calls it the "Direct Infra-Arterial Method." "The trephine opening through the fossa temporalis is sufficiently low, so that the extradural manipulations may be conducted *underneath the arch made by the middle meningeal artery*, which is retracted with the dura, and yet remains uninjured at its two fixed points, namely, at the foramen spinosum of the temporal bone, and the sulcus arteriosus of the parietal. Under this arch, with but slight elevation of the temporal lobe, the entire ganglion and its sensory root may be exposed. This method gives the maximum of exposure, with the minimum of cerebral compression, and injury of the blood vessels." The steps in the operation are as follows:

1. *Formation of Muscle Flap and Exposure of Temporal Fossa.*—A horseshoe-shaped skin incision is made in the temporal region, its base about 4 cm. in breadth, corresponding to the zygomatic arch, and its convexity reaching about 5 cm. above it, but slightly higher than the pinna of the ear. The incision is lower and smaller than the Wagner osteoplastic procedure as adopted by Hartley and Krause. This skin flap is turned downward, some branches of the temporal artery being divided, the underlying temporal fascia is exposed well on to its attachments to the zygomatic arch, and the posterior, or temporal border of the malar bone. An incision is then made through the temporal fascia concentric with and just inside of the skin incision, and at the base of the skin flap it is carried along the middle of the outer surface of the zygomatic arch, through the periosteum down to the bone. The periosteum is then elevated from the bony arch, leaving the masseteric attachment at its lower edge uninjured, and the zygomatic processes of the malar and temporal bones are divided with heavy forceps. An incision concentric with the skin incision is then carried down through the temporal muscle, and the muscle is scraped away from the bony wall of the temporal fossa, to which it has no attachment in this situation, and retracted downward together with the resected portion of the zygoma, and into the space which this bony arch formerly occupied. In this way the lower portion of the temporal fossa, as far down as the attachment of the external pterygoid muscle, below the infratemporal crest is well exposed.

2. *Exposure and Elevation of Dura as far as the Ganglionic Sheath.*—With mallet and gouge a small opening is made through the most prominent portion of the exposed great wing of the sphenoid, enlarged with rongeur forceps to a diameter of about 3 cm., its lower margin carried well down, and including the ridge between the temporal and zygomatic fossa—the crista infratemporalis. The uninjured middle meningeal artery runs on the dura thus exposed, across the opening in the bone as the diameter of its circle. The dura with this vessel may then be lifted almost bloodlessly from the base of the middle fossa until the first point of firm dural attachment of the foramen ovale is reached.

3. *Elevation of Dura With Meningeal Artery and Exposure of Upper Surface of Ganglion.*—By careful blunt dissection, and by working at the dural attachment about the foramen rotundum, and in the line between this point and the foramen ovale, where it is again firmly attached, the edge of the dural envelope which encloses the ganglion and its peripheral ultra-cranial branches may be split, and by careful elevation the entire upper surface of the stellate structure exposed well back on to the sensory root, the ganglion being left in its bed still adherent in the underlying portion of the envelope.

4. *Liberation and Extraction of the Ganglion and Its Branches.*—After the exposure of the upper surface of the ganglion and before division of any of the peripheral branches, these three nerves with the ganglion and trigeminal root should be liberated from the attachments to the base. This is readily accomplished by working with the blunt dissector in the crotches between the second and third divisions, and also along each side of the nerves. After the ganglion and the second and third have been liberated, and can be lifted up by the dissector, it is necessary to free the superior and internal edge of the trigeminal root and first division. These manipulations should be conducted as near as possible to the sensory root, since that is the safest point, and one at which there is less likelihood of injuring the cavernous sinus and sixth nerve. The ganglionic structure may thus be completely obliterated, without division, or laceration of a single branch. With a pair of hemostatic forceps (Kocher's) the structure may then be grasped first back of the site of the true ganglion on the trigeminal root; the three peripheral divisions are in turn held up with a blunt nerve hook and divided with scissors close to their foramina; the sensory root is then evulsed by means of the previously attached pair of forceps.

5. *Closure and Dressing.*—The zygoma and flap of the skin, muscle and fascia are replaced. The resected portion of the zygomatic arch is replaced, and remains in position without wiring, as the masseter is paralyzed. The temporal muscle and fascia are secured in place by fine interrupted sutures at the upper curve of the incision, and a few sutures are taken in the divided periosteum and fascia over the replaced zygomatic arch. In applying the dressing the eye is covered by a large sheet of rubber protective, which bridges across from the nose and forehead to the malar prominence of the cheek, and prevents the pressure of the bandage against the eye. Drainage is not employed. Primary union occurred in all cases, and the resulting scars were very slight. He has not found it necessary to suture the lids, and thinks the local reaction resultant to this procedure would be detrimental in case there was an ensuing keratitis, which is at times unavoidable. The simple protective dressing keeps the eye moist, protects it from dust, and the patients may dimly see through the covering. A Buller shield answers the same purpose.

Prognosis.

1. *The immediate result* of an operation is either relief or death. The relief may be partial or complete. If the entire second and third divisions and their respective portions of the ganglion have been removed, complete immunity will result. If the ganglion has only been partially removed, recurrence will follow.

Death may occur as an immediate result in several ways: (1) Shock, due to loss of blood usually. The use of saline infusion renders this unlikely. (2) Hemorrhage, which it is impossible to control. (3) Sepsis, with meningitis, due to lack of surgical cleanliness.

2. *Remote results* are: (*a*) Recurrence due to an incomplete operation. (*b*) Destruction of the eye due to failure to properly protect it. (*c*) Paralysis of the muscles of mastication, due to removal of the motor portion of the third division. This is grave only when the condition is bilateral. (*d*) Abscess of the brain due to rough handling during the operation.

Mortality.—Tiffany's table of 108 cases (to May, 1896) gives a mortality of 22.2 per cent. According to Carson's table of 100 additional cases (to March 25, 1899) the mortality was 11 per cent., a reduction of one-half (*Med. Rec.*, St. Louis. 1899, XXXIX.). Victor Horsley recently reported 21 cases with two deaths (*Practitioner*, Sept., 1900).

Conclusions.

1. Trigeminal neuralgia is an ascending neuritis, peripheral in origin. The second and third branches, rather than the first, are the ones most likely to be involved.

2. If the disease persists after several months' trial with drugs, electricity, etc., surgical intervention is indicated.

3. If only one branch is involved and the disease is not of long standing, as much as possible of the affected branch should be removed with a view of relieving pain and preventing the upward progress of the disease.

4. If more than one branch is involved, and the pain is severe and has persisted for a long time, the ganglion should be extirpated, all other means having failed.

5. The temporal route should be followed, the Hartley-Krause, or preferably, Cushing's modification of it, being the most rational procedure.

6. Pain will not recur with original severity in more than one or two per cent. of the cases operated upon, or in any degree in more than four or five per cent., and is invariably due to an incomplete operation.

7. It is important to remove the ganglion and its branches intact in order to be certain of the completeness of the operation and to insure a careful and thorough microscopical examination of the specimen.

8. The present mortality is about ten per cent. Increased experience and an improved technic will undoubtedly diminish this mortality, and dissipate the risks of this hitherto most formidable, difficult and dangerous operation.

THE TREATMEMT OF BRONCHITIS IN INFANTS AND YOUNG CHILDREN.

By SAMUEL S. ADAMS, M.D.,
OF WASHINGTON, D. C.

The treatment of bronchitis in infants and young children is so dependent for its success upon the etiology that a few preliminary thoughts seem warranted. Indeed, bronchitis has so many causes and is so frequently the accompaniment of some other pathologic condition that one often is perplexed as to the direction of the application of measures for its relief. It is one of the most frequent diseases and is probably produced by a greater number and variety of causes than any other disease of early life.

It may be primary or secondary. Primary bronchitis may be excited by cold, sudden changes of temperature, exposure to high winds, or great atmospheric humidity, or it may result from the extension of the catarrhal process from the upper air-passages; and it is also common in children suffering from rickets, anemia and malnutrition. In rare instances it is caused by the inhalation of irritating gases and vapors. It may accompany any of the acute infectious diseases; it is invariably present in measles and influenza, common in whooping-cough, scarlet fever and typhoid fever and infrequent in chickenpox and rötheln.

It may also be caused by microbial irritants. It is true that in health pathogenic micro-organisms are suspended in the secretions of the nose and nasopharynx and seldom pass beyond the large bronchi. In bronchitis, however, the ciliated epithelium of the bronchi is destroyed, thus diminishing the resistance to the invasion of such bacteria, so that various pathogenic micro-organisms have been found in the pulmonary alveoli. Numerous experiments have shown that pulmonary tuberculosis can be induced by causing an animal to inspire air charged with tubercle bacilli. If this particular bacillus will invade and infect the air-vesicles, it is not unreasonable to suspect the presence of less virulent organisms in the bronchi and bronchioles.

Although usually sporadic, bronchitis may become epidemic by being transmitted from one child to another by personal contact or through the medium of school-books, pencils, chewing-gum, clothing or, most frequently, by the promiscuous use of the handkerchief. Bronchitis is much more serious in young than in older children, the gravity usually lessening with advancing age. It is dangerous in the younger child because of its greater tendency to invade the smaller bronchi and air-cells.

In addressing treatment to this disease, we should not be hampered by any routine practice, because failure often comes from methods directed to all cases. The individuality of the child should always stand paramount.

Prophylaxis.—Appreciating the fact that the child has a predisposition to catarrhal conditions in general, or to bronchitis in particular, much can be done to prevent him from having attacks by attention to his personal and domiciliary hygiene. Especially in infants should explicit directions be given as to clothing. Many young children are made susceptible to the influence of cold by wearing unsuitable clothing. The maternal tendency is toward too heavy clothing. In cold weather light flannel underwear should be worn continuously, while the outer clothing should be adapted to the changes of temperature. The child should have a daily bath (80°-90° F.), to be followed by gentle rubbing with a coarse towel. The beneficial effects of daily inunctions of oils are more problematical than real. Such practices not only prevent cutaneous excretions, but also soil the child's clothing and often make an attractive baby repulsive. Weak and delicate children are too often confined to the house. Improvement has been marked by keeping the child out-of-doors most of the day. If the atmosphere is dry and cold, it is wholesome, but when damp it would be better for the child to remain indoors where the temperature of the room should vary between 68°-72° F. The temperature of the sleeping apartments of such children should be about 65° F. at night.

A slight coryza is not sufficient to keep a child indoors in pleasant weather. Cool dry and warm dry air are equally beneficial. If the child has fever, it would be better to keep him in bed and watch him, the object being to prevent the extension downward of an inflammation of the upper air-passages. The average case will usually recover promptly if kept in bed in a room well heated and well ventilated, given a simple, nutritious diet, and a mild cathartic—a dose of castor oil excelling all others.

Attempts to abort bronchitis by a hot footbath, free purging and profuse sweating are seldom successful. Such measures may prove injurious unless extra precautions are taken to prevent the child from taking additional "cold" by kicking off the bed-coverings.

Local measures when judiciously applied are often beneficial. Poultices are objectionable because they must be renewed so frequently that the child's rest is disturbed. The effect of the poultice is derived from a chest-jacket of cotton covered with cheesecloth or oiled silk. In many cases, especially where the heart's action is feeble, counter-irritants applied to the chest relieve pulmonary congestion. The turpentine stupe or, as many prefer, the weak mustard paste, may be placed under the jacket until the skin becomes sufficiently irritated, when it should be removed; it may be reapplied every six or eight hours. Blistering is never necessary.

Inhalations of watery or medicated vapors are valuable in relieving the embarrassed respiration by softening the thick bronchial secretion and in applying the medicament to the inflamed part. For infants and very young children this can be accomplished best by placing them under a tent into which the steam from a boiling kettle can be conducted. Older children will inhale the vapors from any one of the many inhalers offered for

sale in the drug-stores. When neither of these methods is practicable the air of the room can be saturated with moisture by having a kettle or pan of water constantly boiling near the child's bed. The following medicaments may be vaporized: Tincture of benzoin (compound), eucalyptol, carbolic acid, creosote, turpentine and terebene. Direct inhalation should last about ten minutes every hour or two; indirect (*i. e.*, through atmosphere of the room) vaporization may be kept up until the atmosphere of the apartment is saturated with the medicament.

Expectorants are not well borne by infants and much care should be exercised in their selection. In the dry stage of bronchitis small doses of ammonium iodide in an agreeable menstruum, to which a few drops of syrup of ipecac are occasionally added, will usually hasten the secretion, thus relieving the swelling of the mucous membrane, rendering the cough less painful and lessening the frequency of respiration. In older children the same drugs in larger doses are beneficial. When the secretion becomes very profuse, the syrup of hydriodic acid is valuable.

Opiates of every description should be withheld as long as possible from infants; but when the cough is harassing and the sleep disturbed, small doses of codein or a few drops of paregoric every two hours, for a few doses only, are justifiable. The older child is often benefited by a small dose of Dover's powder, or codeine added to a palatable mixture. The practice of adding some form of opium to every so-called "cough mixture," regardless of the age of the child, is fraught with much danger. We can relieve or stop the cough, but by doing so we destroy one of Nature's safeguards by which the secretions are removed and the engorged bronchioles freed.

Emetics are seldom indicated, unless the exudate is so profuse, or the stomach so distended with gas from undigested food as to embarrass respiration. In the very young and feeble either of these conditions may be promptly overcome by an emetic of the syrup or wine of ipecac, which is seldom attended by depressing effects.

Cardiac stimulants are required in most severe cases, especially in the feeble. Alcohol in some form is the best and is well borne by children. In cases in which the heart does not seem strong enough to overcome the intrathoracic engorgement a valuable adjuvant will be found in nitroglycerin, which is most effective when administered hypodermatically. While it is injudicious to begin stimulation too early, it would be equally so to delay it until the heart is too debilitated to respond to the strongest stimulants. In bronchitis, or in pneumonia, the heart's action should be jealously guarded.

Respiratory stimulants of strychnine and atropine are required in a very small percentage of cases. They may bridge over the crisis, but should be watched by the physician, and never entrusted to the discretion of either nurse or layman.

Severe attacks of dyspnea and feeble respirations must be promptly met. The passive pulmonary congestion and the overfilled right heart must be relieved, and the compressed and empty air-vesicles reinflated. All of these indications may be fulfilled by Jacobi's plan of flagellation or spanking, which serves the twofold purpose of causing the infant to cry, which induces full, deep inspirations distending the air-vesicles and reddening the surface, which attracts the blood from the distended intrathoracic blood-vessels. The same results may be obtained by H. C. Wood's method of alternate hot and cold douches to the chest. Much less heroic and probably quite as effective as either of these methods is the general hot bath (110-120° F.). Mustard may be added to the water. Oxygen by inhalation may mitigate the feeling of suffocation, but the relief is only temporary.

The treatment of fibrinous bronchitis is at best unsatisfactory. When the exudate causes attacks of dyspnea, inhalations, as indicated above, may soften the membrane which will be expelled by coughing; but an emetic is sometimes more effective in removing the casts. Between the severe paroxysms potassium iodide and hydriodic acid are useful.

Chronic bronchitis is usually secondary to some debilitating ailment, consequently the indications are to treat the primary disease by improving the patient's general health.

1 Dupont Circle.

CLINICAL MEMORANDUM.

FATAL ANGINA PECTORIS, WITHOUT LESIONS OF THE CORONARY ARTERIES IN A YOUNG MAN.

By T. E. BULLARD, M.D.,
of Schuylerville, N. Y.;
With Description of the Heart, and Remarks upon the Case,
By WILLIAM OSLER, M.D.,
of Baltimore.

J. J. H. was twenty-six years old, 5 ft. 10 in. in height, weighed 186 lbs., very strong and active, and was, to all appearances, in robust health just previous to his death. I had known him for fifteen years. His father is a printer and has occasional attacks of epilepsy. His mother is in fair health; his four sisters are all well but one, who has heart-disease.

As a young man, the patient was somewhat eccentric. In about the year 1892 he enlisted. While in the army he engaged a good deal in ball-playing, football and athletics generally. He had been a very heavy smoker. He had not had syphilis.

In the spring of 1895 he was discharged and about this time married. Shortly afterward he returned to his home. Talking with me one day, he told me that he had had an attack of heart trouble while in the army. He did not say that he had had more than one, or that it was serious. He remained in town a short time, when he left.

I heard of him working as a telephone lineman and as fireman on a steamboat. After a few months he reenlisted and was sent to Ft. Keogh, Montana. In the spring of 1896 he was discharged for disability and came home.

He told me that while in the West he had been well for a few months, had marched some hundreds of miles, but that in the winter he was taken with severe attacks of heart trouble. The name of his disease he did not remember. He was in the hospital several months. He described his attacks as coming on at first every other night, then four or five times a week; said there was a most intense pain in the heart, and awful cramps in his arms, that he was given large doses of morphine, digitalis and nitroglycerin. He said that his attacks increased in frequency and in severity, and at one time after he had had an attack he was considered dead, that they were about to remove him to the dead-room when he showed signs of life. All attempts to cure him were despaired of and he was discharged.

A few nights after I had learned from him the story of his winter's sickness, I was sent for to come to his home. I found him in bed, suffering with an intense paroxysm of pain in the cardiac region. His muscles were cramped and he had stopped breathing. He thrashed around in bed for a few moments, and then there seemed to be a cessation of the pain and a relaxation of the spasm. He breathed rapidly, had a few minutes respite, and then the paroxysm of pain and the spasm of the muscles returned. The chest became fixed and for the time being it was impossible for him to breathe or do anything but thrash about in his agony, apparently trying to jar something loose in his chest or heart.

His pulse during the interval was about 130. Just before the paroxysm it decreased in force and frequency to about 100. Sometimes there seemed to be a distinct increase in the force and tension with the decrease in frequency. During the paroxysm the pulse was very faint and slow, and as soon as it was past the pulse immediately acquired a rate of about 130 again. I gave him morphine, digitalis and nitroglycerin. The attack passed off in a few hours.

Seven days later I saw him in another attack similar to the first. This was May 19, 1896. After that he did not have another attack until July 7, 1896, when he had one similar to that which I have described. This was repeated on the 9th, 14th, 17th, 22d, 25th and 31st of this month and also on August 4th, 6th, 9th and 12th. These continued at decreasing intervals and with increasing severity until the next spring when the intervals increased and the severity of the attacks decreased. During the attacks there was no wheezing in the tubes. Exertion did not seem to cause them.

His attacks were more sure to come on and be severe after a cold, damp day. They most frequently came at from 7:00 to 10:00 P. M. I never knew him to have but one severe attack during the day, and on that day he had been walking in the hot sun, and was somewhat excited over a fireman's tournament which he was attending, but this attack was a very severe one.

I have notes of 105 attacks during which I was with him. At times the attacks were of the utmost severity. The pain was so intense that he would lose all consciousness. The muscular spasm extended to nearly all of the muscles of his chest and upper extremities, occasionally to his abdomen and legs, although it was always most severe in the left arm, neck on left side, chest and right arm, named in order of intensity. Some of the attacks lasted as long as five or six hours. There was always a similarity in the attacks, yet they were not exactly the same. Toward spring the pulse-rate in the intermission was not as rapid and was slower just before and during the paroxysm. Time after time his respirations ceased for so long a time and his pulse became so feeble that he seemed to be dead. At times every muscles was in such a spasm that he could be picked up without his bending in the least. Sometimes to pick him up a few feet above the bed and drop him was the easiest way to reestablish respiration, and it seemed that had it not been for the most active efforts, rubbing of the muscles and artificial respiration, he would never have breathed again. This working over him had to be kept up for hours.

In order to relieve his attacks I at first depended principally on morphine. The doses had to be rapidly increased until 8 to 12 grains were given in order to have any effect on the patient. Digitalis, nitroglycerin and nitrate of amyl were used as indicated. The latter never seemed to be of much benefit. When owing to the repeated use of morphine, it seemed to have but little effect, ether was tried. I used to give him four or five grains of morphine and then etherize him. As a rule, after he was nicely under the anesthetic, the spasm would stop, the pulse would remain even, and if the anesthetic was continued for perhaps 30 minutes he would sleep on several hours and have no more pain that night and very seldom the next night. When it became so that it was almost impossible to etherize him I tried chloroform. This seemed to work equally well for a short time. Later, not being pleased with its effect, I discontinued its use. I finally depended almost entirely upon large doses of morphine. In the spring, after he ceased to have his attacks, he showed no evidence of having contracted the morphine habit. After the attacks had apparently ceased he went to New York, had an attack in a saloon, was taken to the hospital, where, according to the papers, the doctors did not know what to make of him. He went to Germany, came back again, worked on a dairy-farm near Boston, doing hard work, then came back to this place again, and remained for a few weeks, when he again left.

This was in the fall of 1897. I lost track of him for some time, but when I did hear from him I learned that he had gone to Europe with a circus.

Whether he had any attacks during that winter, I do not know.

In the summer of 1898 he returned to this place and found employment as a teamster, at which occupation he worked until the middle of winter. During the winter he had a few attacks, but they were not as severe as usual. In the early spring of 1899 he left town again and worked in a paper-mill in New Jersey until the fall of 1899, when he again returned to this place. He had two or three attacks at intervals of a week or more in which I saw him. They were not of the most severe type.

November 27, 1899, he came to my office about 11:30 P. M. and told me that his pain was unusually severe. I immediately gave him several grains of morphine and noted his condition carefully. I saw that it was serious. His pulse in the interval was about 120 to 130. Just before a paroxysm it would slow down during the space of thirty seconds to about 90 and became very faint, then the spasm of the chest muscles suddenly came on. The spasm lasted from one to two minutes during which time he did not breathe. Then the breathing began again, the respirations would be rapid, and his pulse immediately ran up to 120 or 130. After having given 5 grains of morphine, which was two grains more than I had given at any time this fall, and, failing to relieve him, I gave him a little chloroform. I wet the mask only once and held it to his face a few seconds. At this time the muscles of the chest became fixed and remained so, the breathing being entirely diaphragmatic.

It was 12:55 A. M. when I gave him the chloroform. At 1:00 A. M. his pulse was 68; at 1.05 it was 72. At this time I gave him some nitrate of amyl, hoping to help respiration. It did not seem to help him, and the respirations grew more rapid and short until they ceased entirely.

A short, sharp pressure over the ribs, together with artificial respiration, reestablished breathing, which continued for some time. At 1:25 A. M. his pulse was 127; at 1:35 A. M. it was 90. I gave brandy hypodermically freely. Strychnine, nitroglycerin and digitalis were also used in medicinal doses. Hot applications and rubbing were employed to assist in restoring the circulation.

He remained unconscious and the spasm of the chest which had been constant for some hours, relaxed. The attack now continued with intermissions and paroxysms. The pulse during the intermission was about 90. Just before and during the paroxysm it decreased to 60 or less. The interval between the paroxysms grew shorter, the respiration more shallow. The pulse became slower both before and during the paroxysm; during the height of the paroxysm it was at times about 30, and then for 15 seconds could scarcely be felt. At about 6:00 A. M. the paroxysms ceased. His breathing was short, shallow, rapid and regular. The pulse increased to about 120. It was weak and he remained unconscious. The respirations became more shallow, the pulse more feeble, and he died at 6:40 A. M.

At the autopsy we found numerous adhesions between the left pulmonary and costal pleuræ. The heart weighed when removed 14 ounces and 2 drams. It was apparently displaced somewhat to the right, although the displacement may have been post-mortem. The heart was immediately sent to Dr. Osler for examination, who sent the following report and remarks bearing on the general condition.

The heart was of average size for a man of 186 pounds. Considerable amount of subpericardial fat. No pericarditis. The pericardium was everywhere smooth and glistening. The muscle of the left ventricle looked beefy and red; the wall measured in thickness 15 to 20 mm. The papillary muscles were not sclerotic. The mitral segments were thin and showed no marked abnormalities.

Right ventricle, muscle looked red and natural. The tricuspid valves were normal. The pulmonary artery measured exactly 7 cm. across the top of the valves. There was no sclerosis and the valves looked normal. The aorta measured not 6 cm. just above the ring, a small vessel for a man of five feet and ten inches, weighing 186 pounds. The arch only admitted the index finger to the middle of the second joint. The anterior coronary artery was not sclerotic in its course. There were a few flakes of atheroma along its course. Its orifice was large, unusually so, nearly 4 mm. in diameter. There was no atheroma in its immediate vicinity. Posterior coronary artery was not so large; quite free in its course. There was a small, supplementary coronary artery. No atheroma in the neighborhood; no atheroma in its course. No thrombi or emboli in either vessel.

There were a few scattered flakes of atheroma in the aorta. The aortic valves were a little thickened about the corpora Arantii and about their attachments.

On slicing the heart muscle it was red and natural looking; no infarcts; no sclerosis of its muscular fibers nor of the walls of the blood-vessels.

In men under thirty years of age angina pectoris is a very rare disease. There are cases with syphilis in which an acute aortitis is associated with severe and even fatal angina. More common are the cases of a neurotic type in high-strung, nervous persons who have been heavy smokers and given to excesses of all kinds. I have notes of four or five of this sort in young men and have described them in my monograph on angina pectoris (pp. 94-95). In Dr. Bullard's case the extent of the muscular spasm was unusual, although it is not unknown in the ordinary form of the disease. The association of epileptic seizures with angina has been described in the monograph (p. 64). The intensity of the attacks, their long duration, the fatal termination, and the negative condition of the heart and arteries make the case one of unusual interest.

MEDICAL PROGRESS.

Heart-Disease or Epilepsy.—In a few cases, writes F. S. Pearce (*Annals of Gyn. and Ped.*, Nov., 1900), a petit mal with affection of the heart action resembles syncopal attacks independent of the epilepsy neurosis. Organic heart-disease is rarely the cause of convulsions, and then paralysis or death generally follows the spasms. A slow, full, irregular pulse, less frequent and variable, the apparent unconsciousness, a tendency to rigidity without convulsions, and sweating and cold extremities, all favor the hysteroid or epileptoid nature of the attack, while organic heart-disease, cyanosis or cardiac pain point to true syncope.

Harmful Effects of Antitoxin.—While we believe that in the treatment of diphtheria and tetanus, writes W. H. Park (*Archives of Pediatrics*, Nov., 1900) the beneficial effects of antitoxins far outweigh the deleterious, yet eruptions, changes in the blood, and constitutional disturbances occasionally follow the serum injections. These are more marked from the serum of certain horses, but in susceptible persons may develop from almost any serum. The experiments of the author point to the probability that both the antitoxins and the harmful principles are substances having the properties of globulins, and with our present knowledge cannot be separated.

Gastric Surgery.—This important topic is reviewed by G. Kelling (*Arch. f. klin. Chir.*, Bd. 62, H. 2) in the following significant terms: (1) Gastro-enterostomy is indicated when through mechanical interference the normal path through stomach (hour-glass stomach), pylorus or upper duodenum is abnormal. On the other hand, such obstruction in duodenum low down or jejunum high require direct treatment and contraindicate gastro-enterostomy. (2) Rapid regular emptying of the stomach also calls for this procedure which is greatly aided by placing it at the fundus and by closing the pylorus. (3) Patency of the fistula is guaranteed only by shutting the pylorus, which also checks return of food into the stomach. (4) In enteroptosis the posterior gastric wall is the best site of union. (5) With a very large, lax stomach Roux's method is best, with the entero-entero-anastomosis added, except when the gastric wall is so hypertrophied as to provide a spur to prevent regurgitation. (6) Spur-formation arises from a disproportion between the diameters of the fistula and of the intestine, entirely avoidable through proper technic. If the suture is the ordinary continuous type, it is usually safer to add an entero-entero-anastomosis. (7) Along the proximal loop of this secondary anastomosis the distance from the stomach should be not over ten centimeters. (8) The strength of the suture line must not be tested with improper food. Rather large quantities of fluid diet are less dangerous than even small masses of solids which can easily cause perforation. (9) Rapid emptying of the stomach depends upon the fact that for the most part gastric peristalsis ceases when the duodenum is full. (10) Intestinal digestion of albumin and fat is less active, because the stimulus excited by the acids and fat upon hepatic and pancreatic secretions for larger degree fails. (11) Flow of bile and pancreatic juice into the stomach is not necessarily injurious. (12) Hydrochloric acid is less thoroughly neutralized than when it first reaches the duodenum. In weakly subjects with hypersecretion it is therefore advisable to make a very long loop—Von Hacker's method, with entero-anastomosis. (13) The disadvantages of the gastro-enterostomy are in time compensated for, in degree and delay according to the resistance of the organism. Hence the operation should be done, before the causal disease has too greatly reduced the constitution. (14) The most normal method with least after-symptoms is Von Hacker's with the entero-entero-anastomosis. If the pylorus is patent it should be sutured, so as to insure full function of the gastro-enteric fistula.

Uterine Fixation.—The functional results in uterine fixation are apt, says Max Cohn (*Zeitschr. f. Geburtsh. und Gynäk.*, Bd. 43, H. 3), to be somewhat better in the ventral than in the vaginal method. In other details the comparison stands in the following terms, from the material available at the Breslau clinic: Vaginal fixation restores the relation between the fundus uteri and the bladder, displaces the portio vaginalis, is useless in retroflexions with adhesions unless these are freed through the cul-de-sac of Douglas, causes functional difficulties during parturition by changes in the relations, is less dangerous intrinsically, causes no hernia, leaves no scar for intra-abdominal adhesions, has a shorter healing process and fewer subjective sequelæ, and probably more nearly restores natural anteversio-flexis.

Gastroduodenostomy.—E. Villard (*Revue de Chir.*, Oct., 1900) describes a subpyloric anastomosis between the right extremity of greater curvature of the stomach and the left aspect of the descending part of the duodenum. The union may be made in any of the well-known methods and placed either on the anterior or on the posterior surfaces of the viscera. The site considered best, from the author's experience, is the latter, reached by tearing through the right limits of the great omentum, exposing to view the upper anterior surface of the pancreas over which the new union then passes. Advantage is gained by passing a heavy suture one or two centimeters above and below the limits of the vertically-placed anastomosing incision, through the sero-musculares of each viscus, which serve as tractors and as final stout reinforcing sutures when tied. By means of these, in the writer's choice, the stomach and bowel are brought upward, the posterior rows of sutures placed, then the anastomosis is done and, finally, the anterior banks of stitches inserted. Lavage the night and the morn-

ing just prior to the operation is most important, except in those too enfeebled to stand it. Deep ether narcosis is best, as in all laparotomies, because it combats shock more. In the after-treatment, fluids in dram-doses, except water and gaseous fluids, are allowed at once at short intervals, increased slowly in amount and time, until about one week after, when more solid food may be tried. Morphine to complete repose is absolutely advisable for the first two days, unless the subject is too feeble. The value of the operation lies in its brevity, simplicity, safety, respect for the normal physiology by permitting the gastric contents to empty above the biliary and pancreatic ducts, and in its freedom from the double anastomosis (with the increased shock thereof) in the modern gastro-enterostomies. It presents the difficulty of having the deep operative field more or less fixed against the vertebral column; but this is obviated by the fact that gastric cases are usually so thin that the posterior limits of the abdomen are most readily accessible. The indications are *par excellence* cicatricial non-cancerous or spastic pyloric obstruction, old ulcers or early cancers if not too near the outlet, and other conditions in which pyloroplasty or gastro-enterostomy would alleviate or cure.

Early Diagnosis of Ascites.—L. Landau (*Centralbl. f. Gynäk.*, Nov. 10, 1900) says that it is very important to appreciate small quantities of fluid in the abdomen before the usual diagnostic signs become manifest. During the past year he has found the following sign almost pathognomonic. With the patient in the usual lithotomy position, while the axis of the trunk is horizontal, fluid in the pelvis floats up to the uterus so that it feels as if it were on a water-bed and the abdominal and vaginal hands come less regularly together at each side of it. If now the exaggerated lithotomy position is used, with the pelvis much higher than the head, the pelvis will empty itself and its contents resume their normal palpable condition.

Influenza Simulating Whooping-Cough.—The characteristics of this, writes F. Forchheimer (*Archives of Pediatrics*, Nov., 1900) are the fever, its epidemic and contagious nature irrespective of age, and the association with respiratory or gastro-intestinal symptoms. The cough is followed by a whoop, occurs mostly at night but to some extent in the daytime, and is not accompanied by the blue color of the mucous membrane and tongue of pertussis. Ulcers on the tongue and frenulum are not uncommon. In four of the author's cases typical influenza pneumonia developed, in many there was persistent croup, in several edema of the glottis, and in three meningitis. Former attacks of true pertussis or of this pseudowhooping-cough do not confer immunity. The author's treatment consists of quinine in dose of not less than one decigram less than the age in years, and one centigram less than the age in months. When the cough has developed thoroughly, phenacetin or antipyrin gives relief, codeine keeps down the cough, and chloral secures sleep. Belladonna usually disappoints, but at times its effects are gratifying.

Toxicity of Hospital Air.—R. Binaghi (*La Rifor. Med.*, Nos. 219, 220, 1900) gives the result of his experiments in the study of the atmosphere of the hospital and its relation to wound infection. Acting on the theory that a relation might be found to exist between meteorologic factors and the number of germs in the air, analyses were made of the air of the operating-room, wards and dispensary at frequent intervals from November to June, the variations in temperature and pressure of the atmosphere at the time being noted. Petri dishes with glycerin-agar were exposed to the air of the room to be examined at different distances from the floor and for definite length of time; after proper cultivation, solutions of the colonies, in sterile water, were made and injected into the jugular vein of rabbits for tests and for control tests; of fifty-two rabbits inoculated, thirty-one died (59.8 per cent.), thirteen or these deaths being from staphylococcus infection. It was observed that the greatest impurity of the air was found in the dispensary, next in the private corridor, next in the wards, and, lastly, in the operating-room, giving a mortality respectively of forty, thirty, twenty-five, and fifteen per cent.; *i. e.*, the air of the dispensary contained the most staphylococci, while the air of the operating-room contained the least of these germs. The blood of the animals thus killed by inoculation was found to contain in addition to the staphylococci, the bacillus pyogenes fetidus; the bacillus coli; the bacillus typhi similis; the diplococcus of Fraenkel, and the bacillus mucosus. His conclusions are: (1) Staphylococci are the germs most frequently found in hospital air. (2) Their number varies and depends upon the number of people coming into and going out of the room. (3) The influence of temperature and of atmospheric pressure cannot be definitely stated, but the author's investigations proved that the germs were more frequent in the presence of high temperatures and pressures. (4) There would seem to be much justification for the idea of wound infection from atmospheric air, hence the importance of plenty of light and air in hospitals, especially in the operating-rooms, and the advisability of having as few people present at an operation as possible.

Rubber Gloves.—Baron Küster (*Archiv. f. klin. Chir.*, Bd. 62, Hft. 2) states that far from offering adequate protection against wound infection gloves really invite it by complicating the operative machinery and adding another possible source of error. Thorough and conscientious disinfection of the hands by methods which will naturally improve with time is not only simple, but in the long run more efficient.

A Simple Leg-Holder.—J. Kalabin describes a simple device, applicable to any ordinary four-leg table and in any household for examinations,

treatment and operation (*Centralbl. f. Gynäk.*, Nov. 17, 1900). The patient is placed upon any table so that the buttocks come just beyond one end. With towels or sheets tied together to form a rope, the lower extremities, held in universal flexion by an assistant, are maintained so by fastening the rope first to one leg of the table at the patient's head, passing it directly to the thigh, of that side and about it once just above the knee, thence across to the opposite side where the other thigh is secured in the same manner and the rope finally tied to the other leg of the table at the woman's head. The distance between the thighs and the flexion of the thighs on the abdomen are easily variable. The simplicity and readiness of this means commend it. The writer has given it long trial with entire satisfaction.

Menstrual Condition of Average Girl.—In order to determine in what degree normal menstruation exists among ordinary American girls of to-day, an investigation has recently been made by G. J. Engelmann (*N. Y. Med. Jour.*, Dec. 8, 1900) inquiring into the peculiarities of this function as it exists in 5000 girls between fifteen and twenty-six years of age who attend high or normal schools or colleges or are employed in department stores. It was found that it recurred with regularity in not more than 50 per cent. and that it appeared every 28 days in only 30 per cent. of cases. Irregularity increases distinctly with mental strain or physical exertion, the former tending to shorten the intervals, the latter to prolong it. The average frequency in one freshman class was 36.75 days, a prolongation probably due to change of habits. The average duration was 4.6 days, varying from 2 to 7 days. Suffering is present in from 50 to 80 per cent., being less among the college girls than those occupied in stores. Among saleswomen who stand 91 per cent. are afflicted with pain during this epoch and a large percentage are at least partially incapacitated for work.

Lupus and Roentgen-Rays.—W. A. Pusey (*Jour. Am. Med. Assoc.*, Dec. 8, 1900) reports a case of lupus in a woman, thirty-eight years of age, in which a cure was brought about by the use of Roentgen rays. The disease involved all of the lower face on the left side, the chin, and the right face below the angle of the mouth. The ulcers were typical, and the scars were sufficiently rigid to interfere with motion. Tubercle bacilli were found in a section made from a piece of tissue taken from the border of one of the ulcers. The case was clearly one of lupus, not a scrofuloderma. The treatment consisted in repeated exposure of the diseased parts to X-rays. The treatment had to be discontinued several times because of a beginning dermatitis from the rays. At first the treatments were given daily, later with occasional intermissions of three to four days. The length of each exposure was from five to fifteen minutes, and the distance of the tube from the surface varied from 15 to 5 cm. Adjacent surfaces were protected by lead masks. After a little more than three months of this treatment the parts were entirely healed. The writer says that only time can say whether it is a complete cure or not. He calls attention especially to the short exposures required, and the short course of the treatment with X-rays, as compared with the treatment by Finsen's ultraviolet light which requires exposures of an hour each, and a course of treatment lasting a year or two. In this treatment of lupus by Roentgen rays Pusey used no aids except wiping off very unclean ulcers, while Finsen resorted to pyrogallic acid, curetting, and other local adjuvants to treatment. While this method of treatment of lupus by X-rays has been in use in Germany for three years, Pusey says this case is only the third reported in this country.

Diphtheria Antitoxin.—The efficacy of using the antitoxin of diphtheria is again questioned by J. E. Herman (*N. Y. Med. Jour.*, Dec. 8, 1900) who dissects some of the statistics on the subject to show that the apparent decrease in mortality is the result of other causes. The discovery of the bacillus of Klebs-Löffler and the inclusion among the cases of diphtheria of many patients who previously would have been considered as simple "sore throats" rapidly increased the number of reported victims and consequently would have lowered the death-rate. The appearance of the antitoxin at about the same time received undue credit for the apparently beneficial result. Furthermore, the death-rate from diphtheria has for a long time shown an increase extending over many years and then a gradual decline. The introduction of antitoxin happily appeared when the death-rate was at the apex of its ascent in this country. In most of the large cities of England the rate of mortality has increased since the introduction of this remedy, so that the author is inclined to believe that the laurels placed upon antitoxin have been to a great extent unmerited.

Abdominal Hysterectomy.—Robert Sorel (*Gazette de Gynecol.*, Nov. 1, 1900) makes the following points as to this method of removing the uterus: (1) Anatomical considerations show that the cancerous focus beginning in the uterus alone spreads very rapidly to the next adjoining tissues, *i. e.*, vagina, broad ligaments, ovaries, and lymphatic glands, often in a most precocious manner, so that it is quite impossible to diagnose when such invasion has begun. (2) Therefore an operation which purposes radical cure must aim at ablating all these tissues, even including the lymph-glands. (3) Manifestly the only means of doing this well, even theoretically, is by the abdominal route. (4) Since it is not possible to remove *all the* lymphatics, the operation should be practically contra-indicated if more than the uterus is diseased. (5) In order to establish good statistics of this operation some such basis of comparison must be established and even microscopical examination of the uterus and of its lymphatics must be made.

THERAPEUTIC HINTS.

Prophylaxis in Typhoid.—To prevent the disease, writes Delafield, the feces should be received into a vessel and thoroughly mixed with a disinfecting fluid before being emptied into the common receptacle. All soiled clothes are to be soaked in a similar solution. Good disinfectants are:

℞ Mercuric bichlorid..... 8.0 (ʒ ij)
Ac. hydrochlor..... 40.0 (ʒ x)
Aquæ .....4 liters (gal. j)
Or
Mercuric bichlorid..... 8.0 (ʒ ij)
Potass. permangan..... 8.0 (ʒ ij)
Aquæ .....4 liters (gal. j)
Or
Chloride of lime..... 15.0 (ʒ iv)
Water .....4 liters (gal. j)

Mucous Diarrhea.—Often in the milder forms a mustard plaster or other counterirritant to the abdomen is all that is needed, but more frequently it must be followed by tonics and astringents such as:

℞ Argent. nitrat..... 0.13 (gr. ij)
Ext. hyoscyami..... 0.3 (gr. v)
M. ft. in pil. No. X. Sig., one three times a day.
Or
℞ Plumbi acet.....
Ext. opii.....aa. 0.13 (gr. ij)
M. ft. in pil. No. X. Sig., one three times a day.

Constant tendency to relapse demands secretory stimulants, as:

℞ Acid. nitric. dil..... 4.0 (ʒ j)
Tr. cardam. comp..... 60.0 (ʒ ij)
Tr. gentian. comp..... 60.0 (ʒ ij)
Sig., dessertspoonful every four hours.

If the pills above-named fail to check the diarrhea, the following may be used, but not to stop the movements completely:

℞ Acid. sulph. arom..... 6.0 (ʒ iss)
Spt. chlorof..... 8.0 (ʒ ij)
Tinct. opii camph..... 60.0 (ʒ ij)
Syr. zingiber.....120.0 (ʒ iv)
Sig., dessertspoonful every two hours.
Or
℞ Tinct. kino..... 30.0 (ʒ j)
Tinct. catechu comp..... 30.0 (ʒ j)
Mixt. cretæ..... 90.0 (ʒ iij)
Aq. cinnamomi....q. s. ad. 180.0 (ʒ vj)
—*Hare in Practical Therapeutics.*

Renal Colic.—An alkaline diuretic and genito-urinary sedative is:

℞ Potass. citrat..... 2.0 (gr. xxx)
Tinct. hyoscyam..... 4.0 (ʒ j)
Aquæ .....q. s. ad 30.0 (ʒ j)

Every six hours between meals after the acute attack is over. This to be supplemented by copious draughts of hot water until microscopic evidences of blood and gravel have disappeared from the urine. The loins and abdomen are kept dry and warm with a flannel roller. Constipation is relieved by large warm-water or soap-suds enemata, which may follow the administration of calomel, 0.25 (gr. iv), with advantage.—*Bruce in Treatment in Practical Medicine.*

Gonorrheal Rheumatism.—Put to bed only if lower extremities are attacked, says J. R. Hayden, immobilize joints, and apply compresses wet in cold lead-and-opium wash. When the acute symptoms subside apply the Paquelin cautery, or rub in compound iodine ointment, and make firm and uniform pressure by a bandage. If then the fluid remains it may be withdrawn and the joint irrigated with mercuric bichloride, 1-5000. In the chronic stage the joints are massaged and exercised daily, and large doses of potassium iodide administered. The most important thing of all, however, in gonorrheal rheumatism is to cure the urethral lesion.—*Venereal Diseases.*

Primary Laryngeal Tuberculosis.—Surgical intervention is indicated, writes Samuel Bernheim, when the lesion is circumscribed and its extirpation can be early and thorough. Yet usually the focus is too deep and extensive when it is discovered, and resort must be had to medical treatment. In the stage of infiltration the application of carbolic or lactic acid and the inhalation from a pint of boiling water containing 8 to 15 drops of the following:

Balsam peruv..... 10.5 (ʒ iiss)
Alcohol ..... 6.0 (ʒ iss)

is to be preferred. In the ulcerative stage insufflations of morphine and iodoform and applications of iodoformized glycerin may be of use. The best remedy of all is carbolic acid, and the following may be used as spray four times a day:

℞ Acid. carbolic.... 0.30-0.60 (gr. v-x)
Aq. lauro-cerasi..20.0 (ʒ v)
Potass. bromid...30.0 (ʒ j)
Glycerin.... ....30.0 (ʒ j)
Aq. dest.....300.0 (ʒ x)

But no treatment will avail unless means are taken to increase the resisting power of the individual by food, fresh air and climate.—*Revue médicale de la Suisse Romande.*

Postpartum Hemorrhage.—Have patients on back, writes Playfair, and expel contents of uterus by a firm grasp of the hand through the abdominal wall, then gently knead for a long time. If this does not suffice, pass hand into uterus which is incited to contract, and give ergotine hypodermically. The general treatment is that for any hemorrhage. Among the most important excitors of uterine contraction is cold used intermittently by ice-bag over fundus, rectal injections of ice-water in rectum or uterus, or the ether-spray over abdomen. Injections of hot water with a few drops of creolin are valuable, and if nothing else will do, the uterus must be plugged with iodoform gauze. Penrose recommends vinegar. Sometimes the bleeding is from the cervix, and can be stopped by a perchloride of iron swab.—*System of Midwifery.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SMITH ELY JELLIFFE, A.M., M.D., Ph.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

AGGLUTINATION DIAGNOSIS OF TUBERCULOSIS.

WITH the advance in the treatment of tuberculosis an accurate method of very early diagnosis of the disease has become even more than ever one of the great desiderata of modern medicine. The thermometer has done much to reveal the presence of latent tubercle, the Röntgen rays have been of distinct use in institutions, Litten's diaphragm phenomenon has proved helpful to those who have opportunities for exact investigation. The problem of early diagnosis is so important that conservative clinicians still think themselves justified, despite its bad repute, in having recourse to the tuberculin test. But the profession is looking eagerly for some new discovery in this matter, and the further investigation of the possibilities of serum diagnosis for tuberculosis as proposed by Arloing of Lyons seems eminently desirable.

Although the tubercle bacillus is a strictly non-motile organism, Arloing has found that when the blood of a tuberculous patient, in a dilution of about one to ten, is added to a homogeneous liquid culture of the organism, a clumping takes place which is analogous to that which occurs in the Widal test for typhoid fever. The best culture medium for the purpose is glycerinated beef-broth. In animals, this test has, in its inventor's hands, never failed to reveal the presence of tuberculosis, however latent, and has never proved positive in a non-tuberculous case, except once, when one of the forms of pseudotuberculosis without demonstrable tubercle bacilli was found at autopsy. In human beings in 192 cases of clinical tuberculosis the test was positive in about 88 per cent. of the observations. In 130 patients suffering from diseases other than tuberculosis the test was positive in 34 per cent. of the cases. In supposedly healthy persons a positive reaction was obtained in about 27 per cent. of the observations.

That tuberculosis is often latent is well known. Thoracic glands frequently contain tubercle bacilli which lie dormant for years. Whether these cases will render the value of the test nugatory remains to be investigated, but if any clinical suspicions of the presence of tubercle have been aroused it is certainly well to know that there are living tubercle bacilli within the body, even though they may not at the moment be giving rise to any inflammatory process.

The test fails in advanced tuberculous cases only when the disease is progressing rapidly and very little resistive reaction against the invasion of the disease is evident.

It is still a matter of dispute whether the Widal reaction of typhoid fever is a manifestation of infection or resistance. The fact that in cases of typhoid fever, in which the occurrence of the Widal action is delayed, a marked tendency to subsequent relapse has been noted would seem to indicate that the agglutination of the typhoid bacilli is due to the presence of immunifying principles in the blood. The absence of Arloing's reaction in advancing tuberculosis would seem to point to a similar conclusion and demonstrate at the same time the essential identity of the two reactions.

In certain recent cases in France serum diagnosis has rendered possible the differentiation of typhoid fever and generalized tuberculosis, the Widal test proving negative, Arloing's test positive and the autopsy substantiating the conclusion. Blumenthal of Leyden's clinic in Berlin reported at the recent International Congress that the serum diagnostic reaction was of use also in differentiating the character of serous effusions into the various body cavities. In tuberculous peritonitis he has found the reaction to occur very distinctly and to give trustworthy evidence. As the Widal test has made this type of

diagnosis comparatively well known, and as it puts patient and physician to such little inconvenience, it seems eminently advisable that further investigations should be made. This is all the more important because it is especially in latent tuberculosis with good resistance, that is, in the initial stage of the disease as it ordinarily occurs, that Arloing's test promises to give significant information.

THE SAVING GRACE.

A physician, more than any other man, needs to cultivate a margin to his thoughts; or a sort of mental penumbra to which he can assign all facts that are neither black nor white, all conditions that cannot be classified as of either light or darkness.

The young physician begins his work with a mind that is keen to fact and intolerant of vagary. The conscientious physician is all for honesty and faithful work, and cannot bear the ingratiating qualities of the quack. Therefore it is something of a surprise to every self-respecting man to find that the accurate, thorough mental equipment and skill that he has striven so hard to acquire is almost wholly unappreciated by his *clientèle,* and that his success as a practitioner depends on something quite different, a something that the quack, the Christian Scientist, and the herb-doctor alike possess, the ability to recognize and cope with the ignorance and superstition around him.

We will grant that the average well-educated, honest medical man has a bright and shining sphere of influence in a society that represents outer darkness concerning matters of science. The best plane on which the two can mingle to their mutual advantage is in a realm of half light. In other words, before a physician can expect his patients to appreciate his point of view on matters of health, he must make a careful study of their point of view. And what is more, if he is to accomplish anything he must accept their point of view and dim the image of his own perceptions by trying to grasp facts from the standpoint of ignorance.

In an address by Geo. F. Sydenham, on the Vulgar Errors and Superstitions of West Somersetshire and their Relation to Medicine, published recently in the *British Medical Journal,* he sets forth a host of hard, inherited ideas that a general practitioner must assimilate before he can practise successfully in certain parts of the enlightened island.

In West Somersetshire, to the medical idiosyncrasies of which he confines himself, the graduate of a London medical school must accept his place along with the herbalist, the white witch, and the "seventh son" doctor who cures by the laying on of hands on a Sunday morning, both patient and doctor having fasted from the previous night. One man, the seventh son of a seventh son, told this physician that as a boy he never had had a meal on Sunday, as his parents derived a good income by starving him into the proper condition for miraculous cures.

The physician in West Somerset must invariably order the placenta burnt, as the number of times it crackles will foretell the number of children to be born; he must wrap the umbilical cord in burnt rag, although he does not know why, and must submit to having his patient's labor facilitated by the holding of the pepper-pot to her nose. Thorns and inflammation, he learns, are especially susceptible to prayer, which must never be considered superfluous, even after the physician has used his lancet; and he is a wise man who recommends it as far less objectionable in the treatment of hemorrhage and burns than the application of cobwebs and tobacco. When it comes to curing goiter by the touch of a corpse and reducing a hernia by crawling downstairs head first, one feels inclined to pity that man whose rounds take him over the West Somerset moors.

And yet many physicians of this country might collect as varied a list of superstitions even among well-to-do patients; vagaries of diet, of bathing, of clothing, superstitions in which trust in Providence takes the place of hygiene, and prayer serves equally as well as a disinfectant. Personal idiosyncrasies regarding climate; beliefs concerning the nature and cause of ailments that the patient does not possess; to say nothing of the passion for patent medicines; the exalted fervor of Christian Scientists; the calm pity of Theosophists, and the enthusiasm of Vegetarians; all these the physician must continually respect, if he is to be respected.

But what element must he infuse into that mental margin of his make-up, to be all things to all men, and yet be himself an honest man? We advocate the saving grace of humor; that keen appreciation of the ridiculous that never intimates how ridiculous it is, that quiet perception of the grotesque that makes no sign, and that wide interest in men that takes in all their peccadillos, and cranky ideas and intolerances,

without giving evidence of any in return. It is this grace of humor that has saved many a situation. And when we are ever particularly depressed by the inability to make headway against superstition and indifference, we pray for that fine mingling of tact and fact that Sir James Y. Simpson showed when he was violently reviled by the Scotch clergy for using chloroform to relieve the pains of childbirth. Their opposition was based upon the primeval curse, "In sorrow shalt thou bring forth children." Simpson gently reminded them that the first operation recorded in history was performed under anesthesia, since, when God created Eve from one of Adam's ribs, he "caused a deep sleep to fall upon Adam."

PREVALENCE OF OBESITY.

It is positively amazing to see how fat the well-to-do people of New York are growing. We might soften the term, and refer to "unusual abdominal development" and a "tendency to obesity," but we agree with Mr. Gilbert in his satire in the "East India Merchant," wherein he says:

"Upon my word it seems to me
Unpardonable vanity
And worse than that
To call your fat
An adipose deposit."

A series of impartial counts made in the most representative streets, theaters and public conveyances of New York, revealed the fact that among people otherwise normally developed, there is a remarkable proportion with large and protuberant abdomens. There were in a first count of one thousand persons from about twenty years of age upward 281 or over 28 per cent. thus afflicted. In a further series of one hundred taken in the less prosperous eastern district, the percentage was as low as 14, while in another series of 200 counted on the most representative street, Broadway, there were 71 persons with excessively developed abdomens, a percentage of over 35. In the corridors of one of the high-class residential hotels the number of similarly abnormal individuals in a total of 100 was 70, while in a poorer class hotel the proportion was the lowest seen anywhere, namely, 11 in 100. Altogether in a random count on 1500 persons of adult life 447 were decidedly deformed, giving an average of 29.8 per cent.

In applying the discriminating eye to these unsuspecting persons who innocently furnished these statistics, there was no attempt to compare them with the Belvidere standard. Although the normal waist-line should be less than that of the chest, and the abdomen in a straight line with it, yet it has not been forgotten that health and vigor go hand in hand in this climate with a certain amount of fat; and as long as the symmetry of figure was preserved, and the abdomen not startlingly protuberant, the plump and well-nourished were included among the normal. Therefore from this conservative standpoint the rather startling statement may be made that in the American adult, as typified by the New York man, for the men showed this tendency rather more than the women, the undue development of the abdomen is a menace to the physical health of the race.

The cause of this condition, so insidious in its outset, must be sought for in a disturbance of the balance of nutrition. Either overeating alone or overeating combined with insufficiency of exercise is to be regarded as the prime factor in bringing it about. In the metropolis success or a modicum of success means three hearty meals a day, and in very many cases an evening supper thrown in. This of itself would probably produce corpulence, but when there is added to this overfed condition a state of absolute muscular laziness that is bound to increase with a man's success, it is difficult to see a limit to his obesity.

The natural development of the means of transportation has gradually but surely brought about the condition that the most prosperous men live farthest from their business. Not many years ago the majority of persons walked to and from business if the distance was not too great, the horse-cars and busses being altogether inadequate. Later came the elevated railroad permitting of great city development, but distinctly curtailing regular exercise, which became now with business people largely limited to the walk to and from stations. Even that was for many abolished by the advent of the electric cars whose further opportunities for physical repose were readily accepted even at the expense of time.

Not only in travel, but also in domestic and household work, the tendency is to favor the physical being. In the ordinary two- or three-story house of a generation ago, the housewife ran up and downstairs many times a day. In the present era of apartment-houses, the long flights of stairs make the members of the family

more economic of their physical effort, and the cramped quarters of a flat give but little opportunity for exercise in domestic duties; while the wealthy, who live in large apartments and family hotels as well as many in their own huge dwellings, depend entirely on elevators.

The same tendency toward laziness is seen in the distinct diminution of exercise in sports. The middle-aged have derived much benefit from bicycling in recent years, but there is now a noticeable falling off in this respect. Indiscriminate use of the bicycle probably harmed many and has left not a few damaged hearts, but the exercise moderately taken undoubtedly helped to retard the tendency toward fat accumulation. Now the wealthy man has his automobile, and the less wealthy man takes a trolley ride into the country. Golf, the present fad, is too deliberate in its movement to rank with the bicycle as a preventor of adiposity. Moreover it will never become the game of the wage-earner, as it can be played only in the daytime.

Aside from actual interference with the heart from overlying fat, we must consider the extra amount of work necessarily placed upon that organ in maintaining circulation and its increased liability to muscle weakness.

The tendency to grow stout is generally treated as a subject for levity, but when adiposity becomes excessive, especially in the abdomen, it is a pathological condition, for the accumulation of fat there marks the onset of physical decay.

As long as the present trend toward physical inertia exists, we see but small chance of betterment; that which is accomplished must be done along individual lines. The recent fashion among many Wall Street men of walking to and from business is to be highly commended. A more active life is the only radical treatment. It should become a custom with all to find the time for several miles of brisk walking daily. If common sense will not develop the custom it must be developed as a fad; or we shall soon find our prosperous American citizen figuring in the comic papers with abdomen like a Dutch uncle, and, what is more to the point, we shall have a shorter life-limit, and a flabby, degenerate muscleless race of men in our large cities.

Smallpox in New York.—As indicated in last week's Medical News, smallpox cases continue to be reported nearly every day. It is probable that the disease will be present in New York throughout the winter. The vaccinations are progressing rapidly.

ECHOES AND NEWS.

NEW YORK.

President of Lunacy Commission.—Rumors of a change in the personnel of the Lunacy Commission are about. The President of the Lunacy Commission must be a physician of ten years' general experience and of five years of special experience in the treatment of the insane. It is believed that a physician connected with one of the State hospitals for the insane will be appointed.

Presbyterian Hospital Thirty-Two Years Old.—The thirty-second anniversary of the Presbyterian Hospital was celebrated last week in the dispensary of the hospital. The hospital was open for public inspection between 1:30 and 6:00 P. M., and nurses in uniform were ready to conduct people through the building. The anniversary services were held at 3 o'clock and about a hundred persons were present, including all the officers and fourteen of the managers. The address was delivered by the Rev. Dr. Purves. He gave a general outline of the work done by the hospital.

Health Board Presidency.—One of the changes proposed by the Charter Commission removes the provision which now prevents the President of the Board of Health of New York City from being a physician. The new provision does away with the Board as it now exists, and provides for the appointment of one Commissioner, who *may*, or *may not be* a physician, by the Mayor, the appointee to act with the Police Commissioner and the Health Officer of the Port.

Vaccination of Brooklyn Police.—Early vaccination of a general character in the ranks of the Brooklyn police is likely, according to Dr. A. W. Ford, a member of the Borough Health Board. Dr. Ford says that there is considerable apprehension among medical men of a possible outbreak of smallpox in Brooklyn.

Claims of Christian Science.—It was recently claimed by a healer before one of the New York Courts that Christian Science can cure cancer, smallpox, consumption—in fact all diseases.

New Hospitals Needed.—At the annual meeting of the State Charities Aid Association, held in this city last week, it was declared that these additions to the Department of Public Charities were urgently needed. A new Harlem hospital, a separate hospital for phthisis cases, a convalescent hospital, a small municipal lodging-house for women and children, and three nurses' homes, one at the City Hospital, another on Randall's Island and a third at the Almshouse.

Obituary.—Dr. Leroy J. Brooks, for more than twenty-five years one of the leading physicians of Chenango County, N. Y., died last week from uremic poisoning resulting from Bright's disease. He was a member of the county, State and National medical societies, and was widely known.

Dr. Adolf Pramann, one of the oldest practi-

tioners in this city, and well known for his charities, died at his residence, No. 251 East Eighty-sixth Street, on Tuesday, December 11th, from a complication of diseases, leaving a widow, but no children. He was graduated from the University of Würzburg in 1856, and for ten years served as surgeon on the steamers of the North German Lloyd line.

Dr. George H. Elliott, of New York, died at the home of his father, William H. Elliott, in Manchester, N. H., on the 17th inst. He was fifty-five years old and a graduate of Denver Medical College. He served in the Civil War with the Seventh New Hampshire Regiment. He was a member of Hope Lodge, F. and A. M., of New York; honorary member of the Lambs Club, and a member of New York and Denver medical societies. He was also a Commissioner of Lunacy in New York.

Dr. John C. Acheson died at his residence, No. 220 East Seventeenth Street, last week from heart disease, after an illness of six weeks. He was born in this city on October 17, 1832, and was one of the oldest graduates of the University of the City of New York, his class being that of 1853. His brother, Joseph, was the first graduate of the University, class of 1833, and his father was one of the founders. He was graduated from the College of Physicians and Surgeons in 1859, and was one of the first physicians to be employed by the city when the Board of Health was established. He was a charter member of the Zeta Psi and a member of the County Medical Society. Two sons survive him, J. Charles and Harold Stuart Acheson.

Typhoid in Sing Sing Prison.—Warden Johnson announced last week that typhoid had broken out among the convicts in Sing Sing prison. There are now over twenty patients with typhoid in the prison hospital, and additional cases are developing daily. Dr. Irvine, the prison physician, recently held a conference with Warden Johnson, when it was decided to fit up an additional building as an emergency hospital. A wing in the new State building will be used for this purpose. The supply of water to the prison comes from the Croton reservoir, and the water before it is consumed in the prison is boiled.

New Lying-in Hospital.—J. P. Morgan's gift to the Society of the Lying-in Hospital, the fine new building now nearly completed on the north side of Stuyvesant Square, is fully described in the annual report of the Society, made public last week. The basement will be devoted to the outdoor work; the first story to the executive offices, the second to the nurses' department, the third to the septic department, and the fourth, fifth, and sixth stories to wards for patients, containing about 200 beds. The seventh story contains the operating-room, laboratory, kitchen, and laundry, while the eighth story is a continuation of the laboratory, with additional amphitheater seats for the operating-room. The births in this borough are 150 per day, but there are only two hospitals on Blackwell's Island maintaining wards where cases of childbirth are received, and the Emergency Hospital in East Twenty-sixth Street, between Second and Third Avenues, contains only thirteen beds, making, according to the report, a total accommodation at the disposal of the city of sixty-eight beds for waiting women and fifty-six beds for women in childbirth. During the year past the Society, in its present quarters, had 3018 applicants for medical treatment, and cared for 2162; out of this total there were only eight deaths. The average wages received by the husbands of the women treated was $29.84 per month, and the average rent paid $8.53, leaving a balance of about 70 cents per diem on which to support and clothe each family.

Scientific Optics.—Scientific workers the world over have long been familiar with the remarkable results accomplished in the field of applied optics by the genius and industry of Prof. Ernest Abbe of Jena, which have carried that science to more important conclusions than have been reached before and which have developed the great optical works at Jena, thus uniting the theories of the pure scientist with the practical details of modern methods of manufacture. The endorsement which the University of Jena gave to Prof. Abbe's early endeavors has brought great benefits to the University itself and has opened a new field of scientific activity in encouraging trained men to devote themselves to purely scientific problems and to their practical solution. In America, notwithstanding the rapid extension of scientific research, the higher optical field has not seen a corresponding development, for, although there have been large commercial undertakings, they have not shown the tendency to develop along the lines which have been so noteworthy abroad. With the death of the late Herbert R. Spencer the last of the three great American workers in applied optics passed away and as yet no trained American scientists have come forward to supply their places. It is of general scientific interest to note the arrival in this country of one of the trained coworkers with Prof. Abbe at the Zeiss establishment, Hermann Kellner, Ph.D., who has already entered upon his duties as scientific director for the Spencer Lens Company of Buffalo, N. Y. Here he will continue his scientific researches, with especial reference to microscope and telescope objectives. The attempt to establish under American conditions a scientific institution in Buffalo similar in methods to that at Jena will unquestionably be watched with great interest by American scientists.

New York State Hospital for the Care of Crippled and Deformed Children.—This institution, incorporated by the last Legislature, is now open for the reception and treatment of patients. The Hospital is located at Tarrytown, N. Y., at Paulding Avenue and the Hudson River, about a mile south of the railroad station. It has accommodations for about thirty patients. The Board of Managers appointed by Governor

Roosevelt are the Right Rev. Henry C. Potter, Bishop of New York, President; George Blagden, Jr., Secretary and Treasurer; J. Hampden Robb, J. Adriance Bush and Dr. Newton M. Shaffer. The Hospital was established "for the care and treatment of any indigent children who may have resided in the State of New York for a period of not less than one year, who are crippled or deformed, or who are suffering from a disease from which they are likely to become deformed." The following conditions are imposed upon all applicants: "No patients shall be received except upon satisfactory proof made to the surgeon-in-chief by the next of kin, guardian, or a State, town or county officer, under the rules to be established by the Board of Managers, showing that the patient is unable to pay for private treatment. Such proof shall be by affidavit. If there was an attending physician before the patient entered the Hospital, it shall be accompanied by the certificate of such physician giving the previous history and condition of the patient." Patients from three to fifteen years of age will be received for treatment, and all applications will be acted upon in the order of their reception. No patient will be admitted without an examination by and a certificate from the surgeon-in-chief or his assistants. No patient whose condition is such that death is likely to occur in the immediate future, or whose condition precludes a reasonable amount of relief as the result of treatment, will be admitted. Application for admission should be made to Dr. Newton M. Shaffer, Surgeon-in-Chief, No. 28 East 38th Street, New York, who will appoint a time and place for the examination of the patient. Patients living at remote points in the State are referred to the following gentlemen, out of town members of the Consulting Staff: Dr. A. Vanderveer and Dr. S. B. Ward of Albany, N. Y.; Dr. Louis A. Weigel, Rochester, N. Y.; Dr. Roswell Park and Dr. Charles G. Stockton, Buffalo, N. Y., and Dr. Richard B. Coutant, Tarrytown, N. Y.

PHILADELPHIA.

State Medical Examination.—The following is the result of the last annual examination by the State Board of Medical Examiners:

College.	Number examined.	Number failed.
University of Pennsylvania	121	2
Jefferson Medical College	38	4
Medico-Chirurgical College	20	4
Western Penn. Medical College	67	9
Woman's Medical, Phila.	16	0
Baltimore Medical College	12	5
Baltimore University	5	4
Maryland Medical College	4	3
University of Maryland	3	0
Physicians & Surgeons, Baltimore.	3	2
Miscellaneous	38	8

Suit for Maintenance of Indigent Insane.—A novel question of fact has been raised in the suit brought against this city by the trustees of the State Hospital for the Insane at Norristown. The suit is based upon a claim of $52,000, an unpaid balance for the care of indigent insane persons during 1896-97. The charge was $2.00 per person previous to 1899, when it was changed to $1.75. The defence of the city is that while $2.00 was paid during the years named, the actual cost of maintenance, according to the reports of the asylum, averaged $1.90 or less. This difference it is claimed will equal the sum demanded by the hospital. This raises the question as to whether claims based upon overcharges are to be admitted.

Free Hospital for Poor Consumptives.—This organization is now supporting 45 patients in city hospitals and in the Adirondacks. The managers have an opportunity to secure both a city home and a mountain site for a sanatorium at a cost of $10,000, and are endeavoring to raise this amount before January 1st. More than $1500 has already been subscribed. The President, Dr. Lawrence F. Flick, states that since 1884 there has been a steady decrease in the death-rate from consumption in Philadelphia, amounting in all to 33 per cent., and that under the most recent methods of treating this disease 75 per cent. of those in the first stage and 40 per cent. of other cases can be cured.

State Forests as Health Resorts.—Dr. J. T. Rothrock, General Secretary of the Pennsylvania Forestry Association, states in his annual report that "the condition of the forestry movement was never as strong as at present. The State is now in actual possession of more than 100,000 acres of land and is only second to New York. The Pennsylvania Forestry Association has been for years so intimately related to the State Board of Health that we have almost come to regard our work as part of a whole rather than two distinct things. We believe the sanitary influences of either the Hopkins reservation or the smaller one in Pike County are in all respects equal to those of the Adirondack region. We ask the cooperation of the State Board of Health in making known these facts and in enabling us to turn them to practical use in the treatment of our citizens who may be suffering with bronchial or pulmonary troubles. The Forestry Commission in the selection of land for the State reservation have constantly had in mind the possible usefulness of the ground as a source of supply of pure water for our towns and cities." Dr. Rothrock believes that trained foresters should be employed and that there should be a warden for each 5000 acres of land owned by the State.

Pennsylvania Hospital Clinics; Operative Treatment for Cirrhosis of the Liver; Chorea.—Two interesting cases were reported December 12th, post-mortem specimens from one being shown by Dr. A. V. Meigs. Drs. F. A. Packard and R. G. Le Conte spoke of the medical and surgical aspects of the cases. Both cases were operated upon early in October by Dr. Le Conte,

adhesions of the liver and spleen to the diaphragm and of the omentum to the liver and parietal peritoneum being caused by irritating the surfaces with gauze. One patient died within five days of uremia. The other, a man, sixty-three years of age, lived until December 6th. Dr. Packard considered this case a typical one for operative intervention for two reasons: First, the ascites was pronounced, tapping being necessary at increasingly-frequent intervals; second, there was no evidence of relief by the systemic circulation, the veins of the abdominal wall not showing enlargement. The operation, *per se,* was a success, four very large distended veins appearing on the abdomen after a time and the ascites being practically eliminated; but the patient developed typical symptoms of a toxemia of internal origin and finally died. The post-mortem showed a cirrhotic liver and adhesions as stated. Dr. Packard said that operative treatment in these cases offers but little hope of effecting a cure. Toxemia is almost sure to develop sooner or later when the portal circulation is diverted. All the organs of the body are in poor condition in these subjects and do not bear well the operation or the changed circulation. Cases should not be reported as cured within a few weeks or even a few months after operation, as the toxemia may be of slow progress.

Dr. J. C. Wilson recently showed a child suffering from chorea, who had been treated in the hospital one year previously for the same disease. At that time this case and another child having the same affection were in adjoining beds. One was given Fowler's solution, the other compound tincture of cardamom, the rate of recovery being about equal in both cases. The child which was given arsenic has returned, the other so far as is known having had no recurrence. Tincture of cardamom is now being used. Dr. Wilson mentioned these cases as showing that rest in bed is probably of more value than medication.

County Medical Society; Lymphatic and Portal Infections Following Appendicitis.—At the meeting of December 12th, Dr. John C. Munro, Surgeon to the Boston City Hospital, by invitation read a paper upon the above subject. Dr. Munro has met with an unusually large number of cases of infection following appendicitis, his paper embodying the report of many of these cases. The subject is of great interest and importance to the general practitioner, as well as to the surgeon. As the cases of appendicitis that come under the care of Dr. Munro are carefully studied, they constantly add to the evidence of lymphatic and portal involvement due to this disease, the symptoms being chills, tenderness, spasm of muscles, jaundice, etc. Clinically, the involvement is generally retroperitoneal and when openings are made in such cases of lymphatic infection, inflammation and pus are found. The process may lie dormant for a long time, one case developing pain, tenderness, spasm of muscles, etc., eighteen months after an attack of appendicitis. These infections may subside under medical treatment, but it is much better to evacuate the pus. An exaggerated febrile movement before operation, or its persistence afterward, suggests lymphatic involvement. Some of the conclusions reached by Dr. Munro after a study of the cases reported are: (1) Portal infections are by no means rare and are not positively fatal; their severity does not depend upon the degree of appendicular involvement; (2) the process may be a chronic one; (3) lymphatic ones are more common than portal infections; (4) mild cases of both may yield to medical treatment; (5) spasm and tenderness of the posterior muscles, as the quadratus, lumborum, point to retroperitoneal infection; (6) drainage affords satisfactory relief; (7) free incision, especially in portal infections, is always better than aspiration.

Dr. H. A. Hare spoke of the anatomy of the appendicular region and of the favorable circumstances thus afforded for a spread of infection by both blood-vessels and lymphatics. Cases were cited in which chronic colitis was due to irritation of the bowel by appendicular discharges. Also other cases presenting gastric symptoms, such as pain soon after eating, etc., which had been diagnosed as gastric ulcer and finally proven to be infectious from pus in the appendix.

Dr. John G. Clark spoke of experiments which he has conducted with regard to the lymphatics of the peritoneum. Carmine granules injected into the peritoneal cavity of rabbits were found in the circulation five hours afterward. The absorption was through the central tendon of the diaphragm into the retrosternal tissues, although the rabbits were kept upright, no absorption from other parts of the peritoneum being proven. A surprising result was the early finding of these granules in the marrow of the femur. The results would point to the advisability of thorough flushing of the abdominal cavity and leaving in a large quantity of fluid after operation.

CHICAGO.

Favor Reelection of Dr. Egan.—At a recent meeting of the Chicago Medical Society a resolution was adopted urging the reelection of Dr. James A. Egan of Springfield, Ill., as Secretary of the State Board of Health.

Appointment of Dr. Leininger.—The appointment of Dr. George Leininger as the Coroner's chief physician has been announced. He will receive a salary of $2500 a year. He succeeds Dr. E. P. Noel.

To Amend Pharmacy Law.—The Illinois Pharmaceutical Association will ask the Legislature at the coming session to repeal Section 8 of the Pharmacy Law of Illinois. This Section permits the State Board of Pharmacy to allow certain merchants in certain parts of the State to sell patent medicines. It was declared unconstitutional by the Supreme Court of Illinois. Com-

mittees have been appointed to look into the revision of the U. S. Pharmacopœia, another on legislation, a third on trade interests, and a fourth on the Board of Pharmacy records.

Memories of Children.—Investigation of children's memories by Professor F. W. Smedley, of the department of child-study in the public schools, may result in rearranging the schoolwork of the lower grades. If further investigation bears out the present conclusions, children will be taught as far as possible by sound. They will not be asked to learn by use of the eyes until they are older. After examining hundreds of children he has found that up to the age of fourteen or sixteen they remember best what they have heard. After that time sight impresses the memory more than sound. The application of the theory would relieve the eye-strain of young children. Professor Smedley's method of testing children for memory is to read them a series of figures, carrying the number as high as the memory will go. A child may repeat correctly such a number as 1,954,677 and fail if one more digit is added to it. He has found that in reading the figures children under fourteen almost always will remember a higher number than if it were shown them on a card for the same length of time. At the age of fourteen to sixteen the power of remembering through hearing begins to diminish and that of seeing to increase.

Ulcerative Endocarditis.—At a recent meeting of the Chicago Society of Internal Medicine, Dr. B. W. Sippy read a paper on this subject. Ulcerative or malignant endocarditis is in reality a general sepsis with localization of the infective process in the endocardium. It differs from verrucose or benign endocarditis chiefly in extent of pathologic changes and in severity of clinical manifestations. The disease appears either as an acute or a chronic affection. In the acute type the cardiac features may be completely obscured by the widespread localization of the infective process. In differentiating benign from malignant endocarditis the author considered the following points of great value: (1) Etiology and clinical course; (2) temperature; (3) appearance of the patient; (4) blood analysis, including bacteriological examination; (5) hemorrhages; (6) retinal changes; (7) size of spleen; (8) evidence of embolism. Under treatment, the value of prophylaxis, rest, tonics and antistreptococcic serum was considered.

C., M. & St. P. Railway Surgical Association.—This Association met at the Great Northern Hotel December 13th and 14th. Papers were read and discussed as follows: "Some Surgical Notes Gleaned in a Tour Around the World," by Dr. W. S. Caldwell, Freeport, Ill.; "First Aid to the Injured," by Dr. D. Macrae, Jr., Council Bluffs, Ia.; "Ossification or Calcification of the Eyeball," by Dr. Thomas McDavitt, St. Paul, Minn.; "Fracture of the Skull," by Dr. E. M. McDonald, Beaver Dam, Wis.; "Fracture of the Base of the Skull, with Report of Case," by Dr. D. N. Loose, Maquoketa, Ia.; "Fracture of the Jaw, with a Case," by Dr. J. H. Rockwell, Liberty, Mo.; "Fractures of the Lower End of the Radius," by Dr. Ira K. Gardner, New Hampton, Ia.; "Continuous Elastic Pressure in the Treatment of Fractured Patella," by Dr. J. H. Thornton, Lansing, Ia.; "Injuries to the Extremities," by Dr. J. N. Warren, Sioux City, Ia.; "Traumatic Hernia," by J. R. Hollowbush, Rock Island, Ill.; "The Surgical Aspect of the Ferguson Cyclone," by Dr. M. L. Allen, Tama, Ia.; "Gangrene with Cases," by Dr. E. O. Plumbe, Rock Valley, Ia., and "A Case of Brain Traumatism," by Dr. B. F. Dodson, Berlin, Wis.

New Plan for the Appointment of Internes.—The Democratic County Executive Committee recently took action toward changing the method of appointing internes in the Cook County Hospital. Applicants for such positions shall pass a competitive examination conducted by a committee of four physicians, composed of one eclectic, one homeopath and two regulars. The candidates who receive the highest marks are to get the places. The following resolutions were adopted by the Committee:

Whereas, Every two years a fierce contest has been waged for positions on the various medical staffs connected with the Cook County Hospital, and the said contests have engendered a very bitter feeling between the various medical colleges in this city; therefore, be it

Resolved, That the annual contest for positions as internes shall be open to any graduate of any medical school in Cook County. A committee of four, composed of one eclectic, one homeopath and two regulars, the members to be chosen by the respective attending staffs, shall examine on each subject. Each committee shall examine and mark the candidates' papers jointly, and the averages of the four examiners shall constitute the mark for any given branch. The subjects included in this examination shall be the following: Anatomy, pathology, surgery, physiology, medical diagnosis, eye and ear, chemistry, gynecology, skin and venereal diseases, histology and obstetrics. The twenty-four competitors receiving the highest averages in the above branches shall be appointed internes irrespective of the school to which they may belong, and their time of service shall be regulated by the attending staffs.

The number of successful candidates from each school annually shall determine the ratio of patients to be assigned to each staff for that year; that is, if of the twenty-four successful candidates seven be eclectic, eight homeopathic and nine regular, the distribution or allotment of patients shall bear this ratio in the assigning of work to the attending staffs; that is, seven patients to the eclectic staff, eight to the homeopathic staff and nine to the regular staff.

In materia medica and therapeutics a separate examination shall be given by a committee from each of the schools for its own pupils, and the markings of these committees shall be added

to the other averages of their successful candidates in order to determine the relative positions of the competitors from each school. Therefore, be it

Resolved, by the Executive Committee of the Democratic party of Cook County, That the Democratic members of the county board be and are hereby requested to further the objects of the above resolution by every legitimate means within their power.

GENERAL.

Scarlet Fever in the Carolinas.—Scarlet fever has spread over the middle and upper Carolinas. The Board of Health has closed every church in Seneca, prohibiting gatherings of all kinds. Last week Clement College was closed on account of the prevalence of the disease.

Obituary.—Dr. W. H. Jones, United States Navy, retired, died at his home, Bethlehem, Pa., last week of diabetes, aged sixty years. He entered the navy after graduating from the University of Pennsylvania in 1861, and was retired in 1893.

Typhoid Among British Troops.—A question in the House of Commons last week elicited the statement that there had been 15,625 cases of typhoid fever among the British troops in South Africa, and that of this number, 3642 proved fatal.

Gift to Aberdeen Infirmary.—Lord Mount-Stephen (formerly President of the Canadian Pacific Railroad) has given £25,000 to the Provost of Aberdeen, for the purpose of clearing the Aberdeen Infirmary of debt.

Professor Abel Injured.—Dr. John J. Abel, Professor of Pharmacology in the Johns Hopkins University, was painfully injured on Tuesday night by an explosion. He is now confined to the Johns Hopkins Hospital and there is grave concern about his eyes.

American Medical Association Prize.—The Committee on Scientific Research of the American Medical Association desires to announce that it has available the sum of five hundred dollars for the assistance of researches to be undertaken in the next six months, and that the money will be appropriated if applications be received within the month of January, 1901. Applicants should state clearly the character of the research to be undertaken, and the facilities at their command, addressing Dr. H. C. Wood, Chairman, 1925 Chestnut Street, Philadelphia, Pa.

War on Absinthe in Paris.—The Chamber of Deputies adopted unanimously December 10th M. Vaillant's resolution calling on the Government to prohibit the manufacture and sale of all alcoholic liquors pronounced dangerous by the Academy of Medicine. The resolution is aimed at absinthe, the consumption of which has nearly doubled in France since 1894, and now stands at 10,000,000 liters (nearly 6,000,000 quarts) annually.

Smallpox in Michigan.—State Inspector Johnson, representing the State Health Board, has returned from Custer, Mason County, Mich., where a large number of alleged cases of chickenpox have developed. Every case was diagnosed by Johnson as smallpox, and a number of them are virulent. Merchants in whose homes patients are suffering have been going to and from their places of business and every one has been exposed, including many from the country. There are over 100 cases of smallpox at Custer, out of a population of only 300. Strict quarantine has been proclaimed against the village, and there is some talk of a shotgun quarantine on the part of surrounding towns.

Women's Hospital for Canada.—A movement to formulate a scheme for the maintenance, in connection with the Women's Medical College, of a Women's Hospital for Ontario, in which all the operations shall be performed by women surgeons, and the resident physicians shall also be women, is being actively developed. A number of the women doctors of Toronto say that similar hospitals are very popular in the United States, and the mortality in one, in Boston, is very low. It is proposed to get twenty-five-cent. subscriptions for the work from the women of Ontario.

Food Laws of Michigan.—Food Commissioner Grosvenor of Michigan boasts in his annual report, just received, that no State is freer from injurious adulterations of food than is Michigan, that no State has better laws on the matter, and that nowhere are such laws more energetically enforced.

News Items Concerning Third Pan-American Medical Congress.—The Organization Committee has postponed the meeting of the Third Pan-American Medical Congress until February 4, 1901. It will be held from that date until the 7th inclusive. All literature pertaining to the Congress is in Spanish, but occasional news items will be sent to the weekly journals. Delegates can go either by the land routes, which are all *via* Florida, or by the water route from New York. Full particulars concerning these routes, excepting that of the Ward Line steamer from New York, will be found in the *Journal of the American Medical Association* of November 3d. Those coming from south of Washington and west of Pittsburg will probably select the Florida route, while those from the northeast will find the Ward Line more convenient. The steamer "Seguranza" of the Ward Line leaves New York January 30th, arriving in Cuba on February 3d, the day before the beginning of the Congress. The new Ward Line steamer "Morro Castle," holding 135 cabin passengers, leaves Havana on February 9th, reaching New York February 11th. The round trip, everything included, is $60.00. Any one going *via* this route will be absent from New York twelve days. Any of the delegates going down by the Ward Line, who de-

sire it, may by a supplementary payment of $25.00 return *via* Santiago. This trip will take from ten to twelve days, during which time the passengers live on the ship, and have their meals there if they desire. The party goes from Havana by rail to Cienfuegos in one afternoon, there taking the steamer to Santiago, and from Santiago to Nassau, in the Bahamas, and from Nassau to New York. The stay in these different ports will be for a day or more. English-speaking members of the Cuban Reception Committee will meet all steamers on their arrival in Havana and escort the delegates to the hotels assigned to them. The best hotels in Havana are the Telegrafo, Mascotte, Inglaterra and Pasaje. Rates $3.00 to $5.00 a day. The Entertainment Committee, appointed by the City Council of Havana, for the purpose of making it pleasant for the delegates during their stay, have arranged a program which, although as yet not fully determined upon in every detail, is nevertheless one which adds an attractive feature to the meeting. There will be a large ball given at the Tacon Theatre. This will be under the management of a sub-committee and an auxiliary ladies committee. The Committee is sparing no pains to make the ball the great social feature of the week, and one that will be most enjoyable, not only to the delegates, but also to any ladies in their parties. (There will be a banquet given at the same place.) On another day an excursion will be made to the sugar plantation of Mr. LaCoste near Havana on three Government transports. On arriving there the delegates will be shown the manner of growing sugar-cane, gathering it, grinding, cooking and refining the sugar derived therefrom, points of interest connected with the method of making sugar, and life on a sugar estate. Refreshments will then be served, either on the estate, or on the transports returning. These transports will be so arranged for the guests as to give the greatest amount of comfort and pleasure during the trip. On another day there will be a parade of the police and an exhibition of the fire companies, in which they will show the promptness and skill with which they combat any fires taking place in the city. Receptions will also be given by various officials, and private dinners by numerous Cuban physicians to the delegates with whom they are acquainted. The three general sessions of the Congress at which papers of general interest will be presented and addresses delivered by official representatives from the different countries, will be held at the Tacon Theater in Havana. The section meetings will be held in the University on the first floor, and on the first and second floors of the Institute. The delegates from Mexico are at present in the lead, and a large number of abstracts have been received from them. Mention will here be made of the names of the presidents of the different sections, all Cubans, as the presidents are representatives of the country in which the Congress takes place, and the secretaries for the United States. All communications and titles of papers should be sent to the United States Secretary of the Section covering the subject, or to the Associate Secretary for the United States of the Congress, Dr. Ramon Guiteras, 75 West 55th Street, New York. A preliminary program will be published shortly.

CORRESPONDENCE.

ETIOLOGY OF YELLOW FEVER.

Rio Grande de Sul, December 12, 1900.

To the Editor of The Medical News:

Dear Sir:—I purpose once more to avail myself of your courtesy in asking you to publish the following lines:

In my communications on the etiology of yellow fever (made to the Academy of Medicine of Rio Janeiro at the sessions of May 6th and June 3, 1897), in connection with which I have conducted experimental investigations dating back to 1895, I have made the following statements: (1) Yellow fever is a germ disease; (2) the specific agent is found chiefly in the gastrointestinal apparatus and in the spleen; (3) the existence of the bacillus in the blood can only be demonstrated in some cases at the approach of death and post-mortem; (4) besides the fatty degeneration of the liver, which has always been recognized as one of the lesions of the disease, the nutmeg type was found in animals dying of experimental infection; (5) starting from the specific bacillus, it is possible to prepare a therapeutic serum, at once curative and prophylactic.

It is of public notoriety that my applications of serumtherapy, which were crowned with success in the hospital of S. Sebastian at Rio de Janeiro in 1896 and 1897, were made before Prof. Sanarelli had made known his *bacillus icteroides*.

Later, my experimental investigations enabled me to demonstrate that the bacillus of yellow fever is merely a form of the *bacillus coli communis* developed in special life condition.

In his publication, Sanarelli recognizes yellow-fever infection only by way of the air passages; he denies that the bacillus may be found in the gastrointestinal apparatus; he admits that the bacillus may sometimes be found in the blood of patients; he directs attention only to the ordinary fatness of the liver which he compares with that produced by phosphorus poisoning; and, finally, he presents his bacillus as a new microbe.

The outbreak of plague in Brazil inspired a visit to Rio de Janeiro by Prof. Camille Terni, director of the Bacteriological Institute of Messina, Italy. During his residence in Rio this learned bacteriologist has applied himself to the study of yellow fever.

In a conference on this subject, held April 10, 1900, he has established the following: (1)

The *bacillus icteroides* is found chiefly in the gastrointestinal apparatus; (2) in his opinion, it is by this channel that the infection of yellow fever occurs; (3) the bacillus is never found in the blood of the patient; (4) besides the ordinary fatty degeneration, the yellow-fever toxin induces in animals the development of the nutmeg liver.

As you see, the agreement could not be more complete. It is corroboration that establishes the value of scientific investigations. I attach the greater importance to the declarations of Prof. Terni for the reason that he was unaware of the results of my labors, which were, I believe, carefully concealed from him.

The question remains whether or not the *bacillus icteroides* is a form of the *coli communis*. Some day the bacteriologists will give a definite answer and it will then be seen on which side the truth lies.

However it may be, the researches of Prof. Terni strongly confirm my teachings as to the etiology of yellow fever, which I was the first to establish experimentally.

With my thanks, Sir, please accept the assurance of my most distinguished sentiments.

PHILIPPE CALDAS.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LONDON, December 10, 1900.

ALLEGED DEATH FROM THE USE OF THE ROENTGEN RAYS—AN OUTBREAK OF DIPHTHERIA AT CAMBRIDGE CHECKED BY PROMPT MEASURES OF ISOLATION AND PROPHYLACTIC INJECTIONS OF ANTITOXIN—CURIOUS CASE OF TRANCE AT NEWCASTLE—FORECAST OF THE REPORT OF THE HOSPITALS COMMISSION—EXONERATION OF THE MEDICAL CORPS, BUT FAILURE TO PLACE THE RESPONSIBILITY ON THE MILITARY AUTHORITIES—THE DIET OF THE POOR—PROPOSAL OF EDINBURGH PHYSICIAN TO INSTRUCT THEM IN DIETETICS—ARSENICAL NEURITIS OUTBREAK AT MANCHESTER.

A CASE in which death appears to have been due to the use of the Röntgen rays—the first on record—has just been the subject of a coroner's inquest: A woman, aged sixty-eight years, sustained an intracapsular fracture of the neck of the femur on March 21st. To ascertain precisely the injury a skiagraph was taken on April 7th, and as this was not satisfactory another was taken on April 27th. A ten-inch coil and a five-and-a-half-inch spark were used. The photographer asserted that time of exposure was respectively 35 and 45 minutes, but a niece of the deceased alleged that the exposures lasted two hours and two hours and ten minutes. After the first exposure nothing unusual occurred, but after the second the patient complained, on May 4th, of irritation in the lower abdomen and a rash appeared on the following day. The inflammation terminated in gangrene and a slough six inches in length and three inches in breadth formed. The slough was cast off and the surface became healthier, but the ulcer never healed. The patient died on November 5th. At the necropsy the heart was found to be flabby and thin. The fracture had not united. The cause of death was not found in the internal organs. The medical evidence was that death was due to exhaustion from shock, the result of fracture of the femur and exposure to the Röntgen rays. The jury returned a verdict to the effect that "the deceased met her death from shock and exhaustion following the accident and the effects of the Röntgen rays on a weakened system; no blame is attached to the doctor or the photographer." Mr. Lewis Jones, medical officer of the electrical department of St. Bartholomew's Hospital, who was called as a witness, said that he considered the time of exposure reasonable and that the prints were good photographs. The risk of a burn was always present. He had never seen or read of a death caused by the Röntgen rays.

An outbreak of diphtheria which occurred in Cambridge in a population of 50,000 shows the value of antitoxin injections as a preventive. The first case occurred on October 14th and the last on November 15th. In all there were 60 cases in 5 weeks. Nine cases occurred in one school. The school was closed and Prof. Sims Woodhead of the University was requested to act as consulting bacteriologist. The infants attending the school were visited at their homes, bacteriological examinations were made, and prophylactic injections of antitoxin were offered to them. These were accepted in the majority of cases. Antitoxin and a bacteriological examination were placed at the disposal of all doctors for their poorer patients. Four cases, the first of which was traced to the above-mentioned school, occurred in three other schools. These were closed and the children and their young brothers and sisters were examined and offered a preventive injection. Circulars were sent recommending the closure of Sunday-schools. A home was opened for those children in whose mouths suspicious bacilli were found. Here about 30 children who could not be satisfactorily isolated at home were sent. A circular was sent to medical practitioners asking them to keep their patients and suspects under supervision until 3 consecutive bacteriological examinations of their throats had been made. During the outbreak the daily notifications of cases of diphtheria rose as high as 9. The value of the preventive injections is shown by the fact that only one slight case of diphtheria occurred among those treated, although many of them were found to be harboring the diphtheria bacillus, while among the elder members of their families, who had not been treated, many cases occurred.

A curious case of trance is now under observation at the Royal Infirmary, Newcastle, in which the patient, a young man, aged twenty-six years, has been in a state of profound stupor for seven months. He is a clerk who has always been re-

garded by his friends as of a reserved nature, depressed and eccentric. Last March he became unconscious. Up to a few days ago he has made no movement of his voluntary muscles nor showed any knowledge of his surroundings. At night his eyes close in the ordinary fashion of a man going to sleep; they open in the day, but are devoid of intelligence or expression. Even under the strongest electric currents he made no movement. Owing to abstention from food he became "a living skeleton." For some time life was maintained by injections, then he was fed with the stomach-tube, and later he was able to swallow reflexly fluid placed in his mouth. He had been in the Infirmary five months when he first displayed any sign of intelligence. One of the nurses informed him of his brother's death. Tears fell from his eyes, but in no other way did he indicate that he heard the intelligence. One morning he muttered the name of the doctor who stood by his bedside. This was remarkable for the name had not been mentioned in his presence for a considerable time, which pointed to the fact that he was not so oblivious to his surroundings as was supposed. Two months ago food was given to him in the ordinary way and he gradually began to recognize, as far as could be judged by his expression, his surroundings. He was still speechless and motionless. He can speak slightly now, but his utterance is limited to the monosyllables "yes" and "no." He has also begun to move slightly his hands.

An intimation has been made that the report of the Hospitals Commission will be practically a vindication of the Army authorities. Some defects and evils will be admitted, accounts will be described as exaggerated, personal narratives will be declared to be imperfect and unreliable, and the Medical Corps will be complimented on the energetic way in which it combated enormous difficulties. There have been inexcusable neglect, needless suffering and fatalities, avoidable epidemics, and insufficient nurses, necessaries, and comforts—but not in all the hospitals. The Medical Corps was not responsible for these things, for the transport was not under them, but under the local commanders. The absence of necessary beds was not always traceable to anybody. The Government at home sent out the beds, stores, etc., but many of them never reached their proper destination. Hundreds of soldiers died of enteric fever who never ought to have had it at all. They died, in camps to which they never ought to have been sent, from want of proper care and food. The pressure was too great and no attempt seems to have been made to prevent the heavy loss that resulted by such instructions from home or such hearty cooperation between military and medical authorities on the spot as would have been effective. Military exigencies received every attention, hospital exigencies were not promptly dealt with. But the result of the Commission is not satisfactory. The Commissioners seem to have begun their inquiry as if they were investigating a definite charge against a definite body and one so inherently improbable as to give them a strong bias in favor of the accused. The result was foreseen. The Medical Corps is acquitted of inhumanity with which it was never charged. It is said to have made the best of the means at its disposal which was never challenged. But the failure to make the proper arrangements must rest on the War Office and the generals in command. The Commission might have ascertained this instead of merely acquitting the Medical Corps, which is all it appears to have done.

A very valuable piece of work has been done by four Edinburgh physicians who have investigated what the poor eat. Their report was presented to the Royal Society of Scotland by Dr. Noel Paton. Choosing a number of typical families at three wage-rates they kept for some time a record of their expenditure on food and of the kind of food bought. Class 1 was of families with irregular incomes, generally under 100 shillings a week; Class 2 of families in receipt of 110 shillings a week regularly; Class 3 of families earning 150 shillings a week and over. In Classes 1 and 2 the amount of food taken was ascertained not to be sufficient for the demands of the system, not enough to produce the energy required by adults or growth in children. The deficiency was 15.7 per cent. Always below par, these classes are unable to emerge from the state of life in which they find themselves, and, of course, they frequently collapse. Whether the collapse is moral or physical in aspect, poor feeding is a contributory cause. In a large measure poor feeding means improper feeding. The wrong kinds of food are eaten or the right kinds in wrong proportion. In the discussion which followed Sir J. Batty Tuke said that the weekly cost of food per head in the lunatic asylums was 64 cents, while a husband, wife and four children lived in the slums at a food-cost per week of 62 cents. If people of this class could be taught to observe a dietary they would have nothing to spare. After paying for food and rent the family has only 28 cents left with which to pay for clothing, fire and light for a week. There is no hope of tutoring these people in what calls for moral stamina. They are what they are from the weakening of moral stamina—hereditary and immediate—and with that, of course, physical stamina, for the two are in a broad sense inseparable. But among them there is always a proportion of merely unfortunate families of a better class, victims of the accidents of life and capable of rising. It is suggested that for the benefit of these and of the stronger artisan class above them instruction in dietetics should be given.

The outbreak of arsenical neuritis from contaminated beer is continuing to exercise great concern in the country about Liverpool and Manchester. The brewing industries are for the time being paralyzed. Many persons refuse to drink beer of any kind, and the temperance society workers are reaping a rich harvest of converts to the blue ribbon.

FRACTURES OF THE JAW—PUERPERAL INFECTION—EXTIRPATION OF THE HYPOPHYSIS CEREBRI—MORPHOLOGY OF THE STAPHYLOCOCCUS ALBUS—PROSTATIC SECRETION—ERYTHEMA EXUDATIVUM MULTIFORME—AN INVALID'S KITCHEN—DIVERTICULUM OF THE URETER—INVAGINATIO ILEOCOLICA—OLLIVER'S SYMPTOM—RAILWAY ACCIDENTS AND THE NERVOUS SYSTEM.

Warnekros, at the Berliner medicinische Gesellschaft, October 17, 1900, lamented the fact that too little attention in lecture, in text-book and in private practice is given to the important aid the dentist may render in making dental supports in fractures of the jaw. Most of the treatises still commend the old-fashioned fixed splints, whereas almost any dentist can mould and apply the wire splints of Sauer. The author on many occasions has adapted such to the teeth and moulded rubber externally, thus giving a removable and sterilizable splint which will permit considerable chewing. So great is the value of these methods that it would be well to attach a dentist to every regiment, who in war would often be needed and even in peace could frequently render valuable aid.

C. Abel, at the meeting of October 31st, gave the following points relative to puerperal septicemia. There must be a certain number of unavoidable infections during some operations, but the death of from four to five thousand women annually in Germany of puerperal sepsis is appalling. The condition may be advisedly considered after the procedure of Prochowinck on bacteriological grounds, with considerable practical importance, as patients with systemic or local infection, either predominant over the other. In the latter class of case manual dilatation and removal of placental debris are always necessary. Lysol douches are not always advisable. Removal of the diseased uterus is rarely justifiable because so many patients recover without it. Boiled normal salt solution and oxygen-inhalations are of very great value. Local parametric and perimetric abscesses demand free evacuation. The injection of streptococcus serum or of turpentine to cause local aseptic foci is not good practice.

Maas, at the meeting of October 24th, described the results of removing the hypophysis cerebri, the relation of which to acromegaly has been stated. After many attempts, in company with Friedmann, he succeeded in totally ablating it. No visible effect during months of life after it and no evident pathological changes at autopsy were found. The experiments had served little in determining the function of the organ, perhaps because some other viscus undertakes it vicariously. It seems likely that this is not the thyroid gland. Friedmann briefly stated the operative method, namely, through the pharynx and sphenoid bone.

Saul, in speaking of the staphylococcus albus, said that the puncture-culture is really an artificially determined growth. If, on the other hand, instead of the agar-plate, which so soon dries out, fluid agar is taken, which later stiffens, a characteristic tree-like growth after several weeks, which will furnish a definite means of diagnosis, is found. The cocci in the branches are more or less fluidified by necrobiosis, while such as constitute the so-called leaves of the culture-tree are distinct.

Lohnstein, at the Verein für innere Medicin in Berlin, October 15th, said that he has examined the chemical reaction of the prostatic fluid in a large number of subjects who are the victims of chronic prostatitis. In the majority the reaction was acid, in the minority alkaline and in a very few neutral. This chemical feature of the secretion is without visible effect on the life and activity of the spermatozoids.

Heller repeated the fact that many writers have noted a relation between disorders of the genito-urinary and the gastro-enteric systems on the one hand and erythema exudativum multiforme. So pronounced is this condition that some have tried to produce the latter disease by provoking such causal disorder. Thus, Lewin by irritation of the vagina and urethra with oil of savin or silver nitrate regularly caused the skin lesion in one of his patients. Heller had a man under his care who after repeated marital coitus used an injection of creolin. A violent chemical irritative urethritis followed, with a copious purulent discharge, in which no trace of gonococci could be found. Very shortly an active erythema exudativum multiforme appeared, the course of which was completely parallel to that of the urethritis, both declining and after several weeks disappearing together. The recovery was complete.

Von Leyden, at the meeting of October 29th, described the newly-erected "Krankenküche," (Invalids' Kitchen), a recent philanthropic venture, aiming to provide good diet for the sick among the poor primarily and secondarily to sick travelers without family ties and such aid from that source. There are seven forms of diet supplied at the lowest possible cost with a small fee for delivery beyond a radius of two kilometers. The food is carried in suitable heating apparatus. The diet-list is as follows: (1) One-half liter of bouillon and a piece of chicken for 25 Pf. (6cts.) (2) One liter of soup and meat with vegetables or potatoes for 50 Pf. (3) Various soups at choice, meat with vegetables or potatoes or compot for selection, at 75 Pf. (4) Chicken and meat soup or the like; broiled or boiled meat with vegetables or the like; light sweets, 1 M. 25 Pf. (5) Similar but larger variety, 2 M. (6) Single portions from a menu, as meat and chicken, 80 Pf.; vegetables, 40 Pf.; sweetmeats and jellies, 75 Pf. to 1 M. 25 Pf. The institution tries to sell the food at the cost of the preparation of it and the management of the place.

Lippmann-Wulff exhibited a specimen of a ureteral diverticulum taken from a woman, observed during life and previously reported by him

in the *Centralbl. f. Erkr. d. Harn-und Sexual Organe* and finally confirmed at the autopsy. Fifteen years ago the woman's left kidney was removed and a few years later the right kidney was movable and had to be anchored into place. Then bladder symptoms developed and on cystoscopical examination a bulging forward into the bladder space was apparent at the terminus of the ureter, which led to the diagnosis of diverticulum of that viscus.

Schmilinsky, at the Aertzlicher Verein in Hamburg, October 16th, presented a specimen of invaginatio ileocolica. During life the patient presented to the right of and above the umbilicus a rather large tumor, crescentic, with a prolongation about as thick as the thumb into the transverse colon and having a tendency to harden under palpation. In addition there were attacks of pain of variable severity and duration, inanition, vomiting and diarrhea during the colic. The technic of the operation was very difficult and soon after it death from suppurative peritonitis supervened.

Piza brought forward a specimen of *Primula oconica*, well known and used in house and table decorations, as the cause of exanthemata in people concerned in the cultivation and sale of the plant. Although the treatises on dermatology make mention of this plant as one of the existing factors of dermatitis, the average practitioner is not fully aware of it. The form the skin lesion usually takes is that of an acute, follicular or vesicular eczema which is very troublesome in itching, especially at night and over the hands. The cause seems to be the contact of the fluid produced in the trichomes and secreted when the plant is touched. Individual disposition is very important. Gardeners and florists very commonly are the victims. Since this secretion is freely soluble in alcohol, disinfection of the hands and forearms in it is the best prophylaxis. The treatment of this obstinate dermatitis is on general lines.

Jessen discussed the value of the Olliver symptom by means of two preparations. The first specimen was that of a large, intrathoracic, aortic aneurism, probably due to a syphilitic aortitis. Olliver's sign was wanting. On the other hand, the second specimen was that of a diffuse mediastinal sarcoma. In this patient, owing to intrathoracic obstruction, there were apparent edema of the face and chest, pulsation over the manubrium sterni and asymmetry of the radial pulse. Thus the differential diagnosis was very difficult, until given by a metastasis in the right upper lobe. Hence it follows that Olliver's symptom is not sure proof of aneurism, but rather of some change in the space limits of the mediastinum.

Saenger reported his many recent observations of the immediate and remote effect on the nervous system of railroad accidents. Of thirteen patients hurt in 1897, six are now absolutely free from pain or other symptoms; four have slight neurasthenia, sleeping less restfully than previously, have occasional headache and some manifestations of anxiety; two boys have now less mental receptivity than before; and one patient has not been heard from at all. Out of fifteen soldiers injured in 1899, only one now manifests any nervous trouble and this is insignificant. Three railway employes who suffered really very slight injury have all shown marked hysterical manifestations. One engine-driver, badly injured, lost in fourteen days all signs of nervous damage, while another really less hurt showed a melancholic tendency. Severe neurasthenia afflicted one sentinel, probably through anxiety, although he was not hurt himself; similarly a brakeman was attacked through overwork. It becomes, therefore, apparent that in the majority of cases the remote results upon the nervous system are not so bad as have been previously taught. Very few have been rendered unable to earn their living. Not one presents the dreary traumatic neuroses of Oppenheimer, not one has shown the trophic skin- and hair-changes. Only four of the twenty lost consciousness at the time of the calamity, who with the two boys make but six in whom the cerebrum has been manifestly affected. In seven or eight was fear very much marked at the moment of the accident, the majority suffered from excitement after it. The most significant thing seems to be the greater severity of the hysteria and other nervous signs in the employees when compared with private citizens. In illustration there are those who suffered no bodily damage. It is likely that very trying service, loss of sleep and official responsibility were largely the causes. Added to these are the misuse of alcohol and tobacco and poor food which tend to induce early arteriosclerosis among the working classes. The final conclusion is that individual disposition, habits of life, condition of work, actual state of health as to chronic nervous and other diseases, are important factors in which may be found the cause of nervous disturbance as well as in the actual bodily damage.

SOCIETY PROCEEDINGS.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, November 6, 1900.

The President, Frederick Peterson, M.D., in the Chair.

Paralysis Agitans Without Tremor.—Dr. M. G. Schlapp presented this case. The chief features were the rigidity of the muscles, the expressionless face, and the position of the arms, body and hands. The flexor muscles were more contracted than the extensors. There was no tendency to fall in any particular direction.

Paralysis of the Duchenne-Erb Type.—Dr. Schlapp also presented a man who, six weeks ago, had fallen from a bicycle, striking his shoulder. He had been unconscious for five hours. The case was interesting because the anterior

pectoral muscles were affected. There was complete degeneration reaction of the pectorals, biceps and the coracobrachialis, and it was incomplete in the triceps and supinators. There was a peculiarly distributed area of anesthesia showing involvement of the musculospiral and musculocutaneous nerves chiefly. The lower part of the pectoral muscle showed some slight response to the faradic current. The lesion evidently involved the fifth and sixth roots of the cervical plexus. As the anterior thoracic nerves are involved it is not a perfectly typical case.

Drs. C. L. Dana and M. Allen Starr said that they had each seen a similar case.

A Case for Diagnosis.—Dr. J. Fraenkel presented a man, forty years of age, a tailor by occupation, who claimed to have been well up to one year and a half ago. There was no family history bearing on his condition, nor was there any history of any previous acute trouble. About eighteen months ago the man had been pushed roughly off a street car. On awakening the next morning at home he had been absolutely helpless, being unable to move his upper or lower extremities. After six months he had been admitted to the Lebanon Hospital, but had left there, according to the history, unimproved. On coming under the speaker's observation, there had been noted at once the presence of an extensive eczema. On a second examination the shoulder-joints had been found partially ankylosed, and the muscles surrounding them appeared atrophic. There was also atrophy of the supraspinatus and infraspinatus, and slight atrophy of the serratus muscle. The electrical reactions were not changed. A thorough examination of his nervous system proved absolutely negative. There was a peculiar atrophic condition of the skin and a condition of cyanosis on the peripheral parts. There was slight valvular disease of the heart. The diagnosis seemed to rest between rheumatism, a general trophoneurosis and general syphilis.

Dr. B. Sachs said that he had examined this man previously and had been led to think of symmetrical muscular atrophies such as occur after arthritic processes. It was not usual, however, to have them quite so symmetrical. It did not seem to him to correspond to any of the dystrophies or any of the spinal forms of progressive muscular dystrophy. He had had a suspicion that the case might be one of leprosy.

Dr. M. Allen Starr said that when traveling in Norway some years ago he had seen a number of lepers, and had had his attention called to the existence of muscular atrophies in them. The peculiar appearance of the man's face had led him to think of leprosy without knowing Dr. Sachs' view on the case.

Dr. Fraenkel said that very careful inquiry had failed to elicit anything but the most positive statements that the man had been in perfect health up to the time of being thrown from the car. The man had come from the southern part of Russia. A dermatologist had seen the case and had been told that leprosy was suspected, but he replied that the thickening of the face was due to the previous eczema.

Dr. Schlapp said that Bechterew had described somewhat similar cases of "stiff back." There was a possibility of some of the roots being affected.

Dr. C. L. Dana thought this case was one of rheumatoid arthritis and the condition of the skin was the result of an eczema.

Dr. F. Peterson thought it was an anomalous type of chronic rheumatoid arthritis. The fact that the muscles reacted normally would tend to confirm this belief. It was certainly not a spondylose rhizomyelique. This might, of course, be a case in which the spinal cord symptoms were developed later.

Dr. B. Sachs presented the spinal column and the shoulders from a case of spondylose rhizomyelique. The heart also showed previous rheumatic disease.

Spasmodic Torticollis and Its Treatment.—Dr. W. M. Leszynsky read a paper with this title. He said that wry-neck must be classified among the musculonervous disorders. The first case reported was that of Mrs. X., thirty-six years of age, seen by him in 1895. About seven years ago she had suffered from pain and stiffness in the muscles of the back of the neck for several days. She had been greatly worried for a number of years by a protracted lawsuit. There was no family history of nervous disease. In February, 1895, after a fall on the ice, she had begun to suffer from nervous attacks, and in June she had first noticed a tendency of the head to turn toward the left. On examination she was found to be fairly nourished, but anemic. There was frequent and well-marked tonic spasm of the right sternomastoid muscle. Her eyes had been examined and found normal. Her general condition was that of neurasthenia of the lithemic type. She was advised to rest in bed for three months and was given the usual tonics. After two weeks atropine had been injected into the affected muscles, the daily dose being increased slowly up to 1/80 of a grain. At this time the symptoms of atropine poisoning had been so severe that it was discontinued. For a few days after this the spasm of the muscles was decidedly worse. The convulsive attacks lasted about twenty minutes, were very violent and were associated with marked impairment of respiration. Under the use of morphine and potassium bromide the paroxysms had gradually subsided in the course of two weeks. Subsequently various remedies had been employed, but without benefit. The urine was always acid and of high specific gravity. After four months there had been considerable improvement in her general condition but not in the spasm of the muscles. The rest treatment had been continued for some time longer under the advice of the late Dr. E. C. Seguin, but she had finally re-

belled and had gone home. Some months later a brace had been applied, and this had gradually controlled the convulsive movements. The brace had then been discarded, but some tonic spasm in the muscles had still continued. Although there had been no return of the clonic spasm there was still slight occasional tonic spasm of the upper segment of the trapezius muscle. This case pointed to a strong hysterical element, although the patient did not present the usual stigmata of this affection. There was undoubtedly also a lithemic condition.

The second case was that of a woman, twenty-four years of age, whom he had seen on October 24, 1897. At that time there had been a marked spasm which had existed for nearly eight months. She had suffered from migraine for a number of years, and there was no history of trauma. She had been kept in bed and the usual rest cure methods employed for two months. The atropine injections had been used for about two weeks, and they had temporarily controlled the spasm. They had been discontinued after two weeks. She had made a complete recovery at the end of six months, and had remained well since that time.

The speaker said that in 1884 he had recommended the use of atropine in this class of cases. Since then he had employed it in 12 cases, and had found that in many cases it was unsatisfactory, and he now believed it should be looked upon as simply an adjuvant to other measures. The prognosis depends upon the duration and the persistence of treatment. The principal therapeutic feature in every case should be the use of massage and the methodical education of the muscles and their coordinating centers. His attention had first been directed to this valuable method by Dr. Coggeshall of Boston. It was a mistake to resort to surgical measures in the early stages of this disorder.

Dr. C. L. Dana said that in his experience if the wry-neck were pretty closely limited to the spinal accessory and sternomastoid, an early resection would often check the disease and prove most useful. He quite agreed with the reader of the paper concerning the treatment of the older cases.

Acute Ataxia.—Dr. C. L. Dana read this paper, classifying acute ataxia as: (1) The acute bulbar and cerebellar ataxia; (2) acute spinal ataxia, and (3) acute peripheral ataxia due to multiple neuritis of the sensory type. He said that Ebstein had reported a case of acute ataxia with autopsy, and as patches of sclerosis had been found the case had been looked upon as one of multiple sclerosis in an early stage. The peripheral type includes those cases due to the sensory form of multiple neuritis. Up to recent times there had been no definite description of acute ataxia of spinal origin not due to tabes. In 1897 Dr. Strauss had, however, reported two cases occurring in men about thirty-four years of age without history of syphilis or other infection. The description seemed to the reader suggestive only of locomotor ataxia. The cases of acute ataxia first described by Leyden, and still referred to by him as acute bulbar ataxia, certainly had a strikingly characteristic clinical course, so that the name might have some clinical value. Special attention was called to five cases of non-tabetic spinal ataxia which were reported in the paper. The following is illustrative: A man of sixty on January 9, 1890, had begun to feel numbness in the feet, and in a few hours this had extended to the mid-dorsal region. He soon developed a tight sensation around the waist. Ten days later, on coming under observation, he had a staggering ataxic gait, and soon became tired. He could not stand with the eyes closed. He showed distinct loss of muscular sense, but no impairment of the functions of the rectum or bladder. The patient had gradually recovered, and was now well. In another case, that of a man, seventy-two years of age, syphilitic infection had occurred one year previously. Just after recovering from an attack of iritis he had developed a type of ataxia like that described in the preceding case. In two other cases the disease had been in old people, but in neither of them had there been a history of syphilis. They both were victims of overwork, and both had presented symptoms of marked senility. It would seem that these cases were due to senile arterial changes, or due to syphilitic changes in the blood-vessels of the spinal cord, causing hemorrhages or blocking of the vessels, or both. It was possible that in old age the syphilitic virus might lead to attacks on the posterior rather than on the lateral columns, so that the type would be ataxic rather than of the spastic paraplegic type. All of his patients had recovered from the ataxia. The differential diagnosis must be made from an acute onset of a locomotor ataxia.

Dr. Joseph Collins said that his clinical experience had been somewhat different from that of Dr. Dana, so that he had been led to a very different conclusion regarding the etiology. Some of his cases had been in persons of about forty-four years of age without evidence of syphilitic infection. Some times there had been inability to walk in the course of a week. This had been associated with slight incontinence of urine, at times, and with sexual impotence. In these cases there had been none of the cardinal symptoms of multiple sclerosis, and no evidence of cardiac or vascular degeneration. This was a type of case which he had been accustomed to call "acute ataxia." A second class of acute ataxias was acute bulbar ataxia. One of these was a woman, thirty-five years of age who, about August 14th, had begun to complain of dizziness and blurred vision. Shortly afterward, while dancing, she had become ataxic, and then had lain in bed for a long time with marked ataxia and with slight anesthesia of the face. The sense of position had been lost. Later, the symptoms of bulbar involvement—regurgitation

through the nose and bulbar speech—had appeared. The cases of acute ataxia with which he was familiar clinically were those presenting features similar to the ones reported by Dr. Sanger Brown of Chicago, recently, in the *American Journal of the Medical Sciences.* Dinkler had come to the conclusion that the lesion must be somewhere in the corona radiata or in the large basal ganglion.

Dr. Smith Ely Jelliffe said that he had had under his observation for three years a man, thirty-six years of age, who had been infected with syphilis. He was a politician, and at the crisis of a campaign he had suddenly found himself unable to walk. On either side there had been ataxia confined to the lower limbs, and associated with some trouble of the bladder. He had been put on antisyphilitic treatment, and had been practically well in three weeks. He had remained well for a year, and then had had a sudden attack which had resulted in a typical spastic paraplegia. He had eventually died from this, and his spinal cord had exhibited the usual lesions of that affection. In the first attack there had seemed to be an acute ataxia due to involvement of the minor blood-vessels.

Dr. Schlapp reported the case of a man of fifty, an intemperate longshoreman. Three years ago he had developed ataxia and now had a disturbance of tactile and pain sense in the feet. Electrical reaction was diminished. The case looked to him like a neurotabes peripherica. The Romberg symptom was present. The knee-jerks were slightly exaggerated. The case might perhaps be classed as an acute ataxia of the peripheral type.

Dr. Fraenkel said that from the pathological standpoint the condition probably occurred quite frequently, and was often overlooked. He would like some points on the differential diagnosis between organic and functional conditions. The symptoms given by Dr. Dana were not sufficiently objective.

Dr. J. F. Terriberry commented upon the fact that these old people reported by Dr. Dana should have recovered so readily if the vascular system had been so damaged. For this reason he doubted if the vascular system had been especially at fault. Ataxia was a symptom rather than a disease, and the attempt to consider it as anything but a symptom was likely to lead one astray. He was in favor of considering these cases that recover late in life as of neuritic origin.

Dr. Dana said he had not met with the class of cases described by Dr. Collins. Dr. Brown's cases did not seem to be exactly cases of pure ataxia, and hence he had not referred to them. One must distinguish between an ordinary unilateral ataxia such as occurs from acute softening of the pons or medulla and the acute bulbar ataxia of Leyden, which is bilateral. It was a common experience to see old people with hemiplegia and hemorrhage recover in spite of the degenerated condition of the blood-vessels.

BOOK REVIEWS.

A Practical Treatise on Fractures and Dislocations. By Lewis A. Stimson, B.A., M.D., LL.D., Professor of Surgery in Cornell University Medical College; Surgeon to the New York and Hudson Street Hospitals; Consulting Surgeon to Bellevue, St. John's and Christ Hospitals. Third Edition. Lea Brothers and Co., New York and Philadelphia, 1900.

The necessity of publishing a third edition of this valuable book so soon after its almost complete revision in 1899 has given the author an opportunity to bring this volume up to the latest date. Even in so brief a time important advancement has been made in our knowledge of fractures and dislocations, especially in regard to traumatic hematomyelia which is most clearly and fully discussed in the present volume. Nearly all the ordinary lesions are illustrated by beautiful reproductions of X-ray photographs, which now constitute such an important aid in the diagnosis of all bone deformities and displacements. In the 1899 edition the chapters on fractures were almost entirely rewritten and revised, and notable changes made in the treatment of old dislocations. This book now embodies a most complete and comprehensive discussion of the subject of fractures and dislocations and deserves more than ever the reputation, which it has held for some time, of being the best recognized authority upon the subject published in the English language.

Malaria According to the New Researches. By Professor Angelo Celli, Director of the Institute of Hygiene, Rome. Translated from the Second Italian Edition by John Joseph Eyre. Longmans, Green and Co., New York, London and Bombay.

In the Introduction to this work Dr. Manson of England says that it is due to the masterly work of the Italian school that most of our knowledge of malaria has been gained. The researches of Marchiafava, Celli and Bignami opened up the way to the splendid work of Ross of two years ago, and this selfsame Italian school was the first to confirm his work, to extend it and to throw themselves with energy into the indicated hygienic measures.

With reference to the work itself, it is not too much to say that it is, of the shorter monographs, one of the best that has been published. The history, economic consequences, etiology, sources of infection, life of germs in the environment, vehicles of infection, path of penetration, etc., are considered under the general heading of Epidemiology. Part II., on Prophylaxis, discusses the means of prevention, first concerning the cause itself and, secondly, those means which are directed against the predisposing causes.

As a thorough, up-to-date and readable summary of our present knowledge of malaria the work can be most cordially recommended.

Diseases of the Eye, Ear, Nose and Throat. A Pocket Text-Book of Diseases of the Eye, Ear, Nose and Throat, for Students and Practitioners. By William L. Ballinger, M.D., Assistant Professor of Otology, Rhinology and Laryngology in the College of Physicians and Surgeons, Chicago, etc., and A. G. Wippern, M.D., Professor of Ophthalmology and Otology in the Chicago Eye, Ear, Nose and Throat College. Lea Brothers & Co., Philadelphia and New York.

This series of manuals forms a good index of the modern advance in medical book-making. While compendiums were notably careless in their make-up some years ago, these are models of the best book-making. The illustrations are clear, well reproduced and really illustrate. The colored plates are artistic reproductions of important anatomical preparations. There is but one fault to find with the book and that is that its 500 odd pages of matter on heavy paper should be crowded into a cloth binding. The contents of the book fit it eminently for frequent consultation and it would seem that for this purpose these pocket text-books should be bound in some more durable material.

The work of compression necessary to present such large special subjects as the eye, ear, nose and throat in a small compass to the general practitioner is very well done. The chapter on Retinoscopy, for instance, is a model of clearness, although contained in less than five pages of the book. The determination of the hearing capacity by various methods is very practically discussed and in a manner that cannot fail to be of great help to the busy practitioner who sometimes finds himself in the necessity of determining the quality and range of the hearing power. This dictum, for instance, is a sign of the practical and conservative attitude adopted, no matter what amount of improvement.

The chapter on Diphtheria is notably good, as is also the treatment of various pathological conditions connected with all the tonsils. There are necessarily signs here and there of the compression that had to be practised in order to bring the extensive subject-matter within the scope of a book of this size, but it is difficult to see where and how this little text-book could have been improved.

Practical Urinalysis and Urinary Diagnosis. A Manual for the Use of Physicians, Surgeons and Students. By Charles W. Purdy, LL.D., M.D., Queen's University, Fellow of the Royal College of Physicians and Surgeons, Kingston; Professor of Clinical Medicine at the Chicago Post-Graduate Medical School. Fifth Revised and Enlarged Edition. With Illustrations, Including Photo-Engravings and Colored Plates. Philadelphia, New York, Chicago: F. A. Davis Company, 1900.

In this volume the author bridges the gap between the purely clinical aspects of urinology as it is treated of in works on medicine and the descriptions of chemical reactions and technical manipulations forming the main bulk of books on urinalysis *per se.* The clinician and the chemist are placed on common ground and their joint knowledge combined in a way that cannot but be helpful to the student and of service to the practitioner for reference. A notable feature is the beautiful way in which the author has elaborated the subject of centrifugal analysis, and it is mainly to his exertions that we are indebted for practical working methods for determining by this means the quantities of chlorides, phosphates, sulphates and albumin in urine with a degree of accuracy equal to that of any method and at an enormous saving of time. The significance of this is apparent when it is known that by the use of the centrifuge and the author's tables a fairly complete analysis of urine, both quantitatively and qualitatively, may be made in from twenty minutes to half an hour, while formerly it took twenty-four hours' time. The section on urinary diagnosis is equally complete and valuable and presents logically systematized information which to obtain otherwise would require a search through many volumes. In this, the fifth revision, much new matter has been added and a book produced that deserves unqualified praise.

BOOKS RECEIVED.

A Manual of Materia Medica and Pharmacology. By Dr. D. M. R. Culbreth. Second Edition. 8vo, 881 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. $4.50.

Malaria According to the New Researches. By Dr. Angelo Celli. Translated by J. J. Eyre, M.R.C.P. 8vo, 275 pages. Illustrated. Longmans, Green & Co., London, New York and Bombay.

Studies in the Psychology of Sex. By Havelock Ellis. 8vo, 275 pages. F. A. Davis Company, Publishers, Philadelphia, New York and Chicago.

Obstetrics. A Manual for Students and Practitioners. By Dr. D. J. Evans. 8vo, 409 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. $2.25.

Report of the Commissioner of Education for the Year 1898-99. Vol. I. and II. Washington, D. C.

Transactions of the Texas State Medical Association. Thirty-second Annual Session. 8vo, 400 pages. Illustrated. Austin, Texas.

A Practical Treatise on Medical Diagnosis. For Students and Practitioners. By Dr. J. H. Musser. Fourth Edition, Revised and Enlarged. 8vo, 1104 pages. Illustrated. Lea Brothers & Co., Philadelphia and New York. $6.00.

Kroll's Stereoskopische Bilder zum Gebrauche fuer Sc[illegible]elende. Dr. R. Perlia. Fuenfte verbesserte und ve[illegible]ehrte Auflage. Leopold Voss, Hamburg.

Dis[illegible]ection and Disinfectants. By Dr. H. M. P[illegible]ken. 12mo, 87 pages. Trade Periodical Com[illegible]y, Chicago, Ill.

[illegible]yclopedia Medica. Editorship of Dr. Chalmers [illegible]atson. Vol. II., Brachial Plexus to Digestion, 562 [illegible]ages; Vol. III., Diphtheria to Food, 546 pages; Vol. IV., Foot to Hernia, 534 pages. Longmans, Green & Company, New York, London and Bombay.

Biennial Report of the Department of Health of the City of Chicago. For the years 1897 and 1898.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXVII. NEW YORK, SATURDAY, DECEMBER 29, 1900. NO. 26.

ORIGINAL ARTICLES.

THE NITRITE TREATMENT IN SYPHILIS.

BY WILLIAM BROWNING, M.D.,

OF BROOKLYN, N. Y.;

PROFESSOR OF NEUROLOGY AT THE LONG ISLAND HOSPITAL COLLEGE.

THE frequent occurrence, varied character and chronicity of syphilis make it a disease that often taxes our therapeutic resources. The common and more useful remedies have their greatest potency in the early and middle stages, while the tertiary period, with its varied and indirect manifestations, we are less capable of combating. This leads us to seek means for improving the corresponding lines of treatment.

The use of the nitrites in this disease originated in two quite independent sources and with widely different objects in view. While the present article is intended to deal with only one of these methods, still, for the sake of completeness and to avoid misunderstanding, a brief notice will first be given of the other plan.

Induced apparently by certain chemical considerations which it is not necessary here to detail, Petrone of Naples essayed the subcutaneous use of nitrites in syphilis. His two cases were described under the title "Sull' uso dei nitriti nella cura delle malattie infettiva," in *Riforma Medica* for August, 1895 (v. *Giornale Italiano delle Malattie Veneree e della Pelle*, Sept., 1895). His initial dose was 5 to 10 centigrams and this was increased to a maximum of half a gram daily. It was given hypodermically in solutions of two to three per cent., a strength of five per cent. being often painful. In one of his cases there was a combination of paludism and syphilis. In this case treatment lasted thirty days. The second case was that of a woman of twenty-two years affected with hereditary syphilis. The treatment was continued twenty-six days. A complete cure was claimed. Sprecher of Turin, however, reported the following year less favorable results in his twelve cases. In his hands it only seemed to relieve osteocopic pains somewhat and caused much local discomfort.

Recently Prof. Darkschewitsch of Kasan (reported in *Neurolog. Centralbl.*, April, 1900, p. 378) related his favorable results in tabes dorsalis. He followed Petrone, injecting once a day one centigram of a one- to three-per-cent. solution of the nitrite of sodium in water (starting with the one-per-cent. and increasing). The course in each patient extended to not less than eighty injections. Under this treatment he observed the shooting pains decrease, the ataxia and weakness of the lower extremities improve, not rarely, amelioration of the symptoms in the pelvic organs, especially the bladder, and increase of the body weight. In cases of pronounced optic atrophy the papillary arteries filled up to the normal, and vision improved. Of course the usual head-manifestations of the drug were noticed.

Very likely other reports on this method have appeared, but the above references suffice to indicate the plan and the results accomplished. The expectation of that method, as claimed by its originator, is that the nitrite will act directly as a remedy in itself for the disease.

The other method of using nitrites in syphilis originated with the writer. It was first described by him in an address before the Medical Club of Brooklyn, June 24, 1895 (published in "The Normal and Pathological Circulation in the Central Nervous System," 1897, pp. 166-9, from which quotations below are taken). Before writing on the subject at all, the plan had been given careful testing at my hands and those of medical consultants. In the period that has since elapsed much additional experience has naturally been gained. The whole matter can be better presented by specifying the main facts and conclusions than by giving series of cases.

A correct understanding of the way this remedy acts in syphilis will prevent disappointments and enable us the better to secure desired results. The European view may have some warrant, but that point it is not necessary to discuss here beyond noting that in several of the cases reported abroad it is far more probable that the good obtained depended on the principle for which I contend.

My reason for resorting to this method is the widespread tendency of syphilis to cause arterial interference. This usually means a narrowing of the lumen, either from organic changes or at times by vascular spasm. The recent work of Abramow (1899) and of Berkley (1900) corroborates previous views that in these processes the muscular layer of the artery remains relatively long intact. To meet this, symptomatically at least, it was natural to have recourse to the group of vasodilators, and of these the nitrites stand at the head. My purpose was and is to have the drug act in a symptomatic manner, and not as in itself a specific cure for syphilis.

"It should be borne in mind that often the so-called specifics for syphilis will develop their desired local action only after the vessels have been dilated. When they are almost closed it is evident that little blood, and consequently little of the medicament can reach the imperiled point.

It is necessary, if possible, to open the vessel-path, and, while keeping it open, follow up with the more direct specifics. . . . We all know that at times an undoubtedly syphilitic process fails to respond well to treatment. Some of these cases can be reached by this plan, and very many by a less amount of specific than otherwise."

The method employed by me aims first to secure the temporary safety of the patient where there is immediate danger, and then more widely as a means by which to get better results from routine specifics. "For this purpose the hypodermic use is unsuited. Prolonged action without untoward effects is that here desired." The hypodermic use masses the drug's effect, but correspondingly shortens its action. We want it, on the contrary, as nearly continuous as possible. Hence the more volatile and fleeting preparations like nitrite of amyl are of limited value, and in only a less degree does this hold for nitroglycerin.

My earliest and greatest experience with this means has been in cases of syphilitic disease of the brain arteries. In many of these cases it is perfectly practicable to make a diagnosis, even so far at times as to approximate the vessel or vessels chiefly involved. Most often doubtless it is the Sylvian or its branches or the basilar. But the main thing therapeutically in such cases is to determine the nature of the process affecting our patient, the exact vessel being immaterial except in so far as it may help to insure the general diagnosis. There are nearly always prodromal warnings. Where these are not heeded we know but too well the danger of complete blocking and irreparable necrosis in the threatened brain area. The immediate results obtained here by the use of nitrite are strikingly satisfactory to patient and physician. Threatening symptoms are promptly relieved, the case loses its emergency aspect, and we can proceed more deliberately with the treatment.

Somewhat allied to this type are those cases of depression melancholias and even suicidal tendencies that are evidently syphilitic in origin (not, of course, including the syphilophobics). Here the buoying qualities of the nitrites are very marked, and will sometimes be life-saving.

By degrees a variety of cases, either somewhat different in character or in other parts of the body, but involving like principles, have come under notice. These serve to more clearly establish the method and extend its scope.

In the so-called parasyphilitic changes, when once well developed, the nitrites are not of great use. Still, as the vascular element plays quite a part in their development, much assistance can be gained by the employment of this agent in all the initial and early stages.

So also in the early stages of progressive dementia nitrites often form a very useful adjunct. They meet a natural indication in this trouble independent of its specific or non-specific origin. The good effects are, however, temporary unless enforced by hydriodic acid, brucine and other aids. Still, as a whole the nitrites perceptibly improve the poor therapeutics of incipient or developing paresis. In some cases we seem able with this additional help, to arrest its progress, and even the physical signs may largely abate. Inasmuch as this disease is pathologically of vascular origin it is easy to see that it might be specially influenced by nitrites. Rare cases have been described where paresis has been most favorably influenced by trephining, blistering of the scalp, or inflammations about the head. It is evident that these must have acted largely through the vascular arrangements. In the nitrites we have an agent acting in the same sense and that can be perfectly regulated in dosage.

On the diabetes (glycosuria) of old syphilitics this agent has repeatedly shown its value. In one case seen last spring with Dr. H. C. McLean, this plan, including the subsequent free use of iodide, led to the entire disappearance of this symptom.

Of spinal disorders the one where it has proven particularly useful is the rather common spastic form of spinal syphilis described by Erb (*Neurologisches Centralblatt*, March 15, 1892). He did not determine its anatomical basis although suggesting an affection of vascular territories, and I am not aware that anything definite is known on that point. It is certain, however, that the nitrites aid materially in handling it, although this is otherwise, next to gumma, the most amenable form of spinal syphilis. Very likely it depends on spinal arteritis and hence the good effects obtained from nitrites.

It is possible that the once favorite use of nitrate of silver in tabes depended for any good it may have done upon the slight nitric element rather than upon the silver. At the same time it has not been my good fortune to see any very striking results from the nitrites in this affection, although in some cases useful, and in every case worth trying.

In gumma of the brain or cord nitrites help materially to get the desired rapid action of mercury and iodides.

Specific troubles outside the central nervous system, especially when accompanied by pain, may be thus favorably influenced. For instance, in the recent case of a young man with known hereditary taint, the symptoms of a sharp first attack of appendicitis yielded readily to this means after complete failure of the ordinary remedies.

The nitrites are indicated in all syphilitic disease of the arteries, as a rule in all specific affections attended by pain, in all syphilitic brain troubles, and especially in the later and hereditary forms of syphilitic disorder (cerebral, spinal, peripheral). This lumps clinical indications rather than differentiates them, but for present and practical purposes it may suffice. *With these indications goes the mandate to immediately employ such other and more directly*

specific agents as the case demands. The title of this paper is intentionally made Use *in* Syphilis, not *for* Syphilis. It is understood that the glycerin and erythrol preparations are nitrates. But it is what is known physiologically as the nitrite action that is developed and hence that term is used in this article.

Administration.—In the use of the nitrites certain by-effects, in general unpleasant, are met with more or less frequently. The frontal pressure, fulness of the head and even headache are presumably inherent, if we succeed in getting the desired physiological action, no matter which preparation is employed, and hence we may not expect in any way to materially avoid them. Whether the drug acts quickly or slowly so long as it acts forcibly these secondary effects must be expected. A certain tolerance usually develops, possibly the expression of systemic accommodation. In the case of the rapidly-acting nitroglycerin, the head-manifestations may be more sudden and transient, but the difference is only one of degree.

Not so, however, in the case of the peculiar gastric discomforts that soon become intolerable to many patients. These are evidently due to the decomposition of the nitrite in the stomach. The nitrite of amyl need not be considered, as its action is too evanescent. Of the other preparations, nitroglycerin alone possesses in my experience practical freedom from this objection (due presumably to the fact that it goes unaltered into the circulation). For that reason this preparation is, for any prolonged periods, the one we are often compelled to employ. Nitrite of sodium may be tried at the start and in rare cases continued some time. Usually, however, the complaints are soon so urgent that a change has to be made. Some of my colleagues using these preparations find less complaint against them.

Since the more general accessibility of the tetranitrate of erythrol I have made considerable use of it. Possibly the gastric complaints are somewhat less or more delayed than in the case of the sodium salt, but there is no great difference in the two on this point. Lethargic and stuporous individuals can sometimes continue it awhile. The employment of this preparation is based on the results obtained by Bradbury (*Lancet,* 1895, II, pp. 1205-1213) who showed that its peculiar nitrite properties are slower and more lasting in their effect, beginning in half an hour and continuing several hours. He recommends doses of a grain or more, given either in solid form or dissolved in alcohol. In my work doses of half a grain are quite sufficient at the start, and even that amount may soon be complained of. I find that clinically, as was shown by Bradbury experimentally, it does not cumulatively lose its effect, as is the case with nitroglycerin. Its slower action is its other most desirable quality.

The desideratum at present is some vasodilator at least as slow and prolonged in its action as the erythrol salt, and at the same time as free from gastric disturbance as is the glycerin preparation. Doubtless some of our chemists or workers will find an article free from drawbacks, or perhaps some combination in administration that will prevent this without invalidating effectivity. Meanwhile, although we can begin with one of the sugar combinations (mannitol nitrate having also been recommended) or the nitrite of sodium, we shall usually have to fall back on nitroglycerin for prolonged use, despite its lack of needed staying qualities. Occasionally we need at the start a very prompt agent, and then of course nitroglycerin is just in place.

The method of administration is also of importance. For my plan the hypodermic use is quite unsuited. That only makes the action of the nitrite the more temporary, and leaves the course of events unaffected until the next dose. It is moreover often painful, but that is not the essential objection. As nearly a continuous action as possible is what is in order and for that purpose administration by the mouth answers best. One to two grains of sodium salt are usually sufficient, at least for the earlier doses.

All of these agents are highly explosive if improperly handled. This should be borne in mind in making combinations, a practice not to be recommended when dealing with the nitrites. The sodium salt should be given in solution, while the sugar preparation is available in tablet form.

THE FAILURE OF THE CONSENSUS JUDGMENT WITH REFERENCE TO TUBERCULOSIS.

By CHARLES DENISON, A.M., M.D.,
OF DENVER, COLO.

It has been a custom with many physicians to send out circulars of questions to the profession expecting through the opinions thus obtained to aggregate average results. But the majority vote settles nothing in the scientific investigation of undetermined conditions, except to show that the greater number of minds are working in the same groove, and the decision of many of those who do give an opinion is influenced more by the confidence they happen to have in the judgment of another than by any knowledge they have gained through personal investigation.

As to tuberculosis there is unanimity enough in the medical profession, such as it is. But this unanimity reminds one of a band of antelope beguiled by the wily hunter to investigate his red bandanna suspended on his ramrod near his hiding-place. We need more originality in method and independence in investigation in order to solve this tuberculosis problem. Tuberculosis congresses are assembled, symposiums on sanatorium[1] and other methods of treatment are held,

[1] The word *sanatarium* is here used to mean a "closed" institution for the treatment of invalids, in contradistinction to *sanitarium*—a health station or health resort.

and the ways of limiting and destroying the germ are discussed. Old "saws" are refiled, backed by the agreement of a multitude of witnesses, but we do not seem to get very much nearer the root of the matter.

Some twenty-seven years ago I thought I had discovered the way to solve the problem. I undertook to get the consensus of the experience of 3500 carefully selected physicians representing the whole United States upon the subjects of inheritance and climatic treatment The causative conditions and after-longevity of consumptives of different varieties, ages and stages of disease were to be determined for bad, medium and good climates. Then even life insurance companies could calculate their income savings through the change of residence of their invalidated insured. The replies to this circular of fifty questions were generous and interesting. But Professor Lusk of New York wrote, after spending half a day giving his own answers, that he would give more for an individual opinion than he would for the combined answers of the whole medical profession. This was a discouraging criticism of the consensus method. Its wisdom, however, was verified by the necessity to practically abandon the original plan, because of the neutralization of the evident good work of some reporters by the unreliable, indefinite and questionable experience of their confrères, or of those from other quarters.

Just now the prevailing opinion among medical men appears to be in favor of home management and the local hospital treatment of tuberculosis, and every consideration seems to hinge on infection as its cause. My reasons for opposing this consensus judgment are as follows: (1) There is a decided advantage in climatic change over the home or the local sanitorium treatment, and (2) the germ origin of tuberculosis is not the sole cause of the disease, and so is not a sufficient foundation for either its educational or legislative control.

1. There never has been found anything more potent for actual cure than a seasonable and decided change of residence and occupation, involving, as it does, getting away from the whole of the previous environment, which, more than anything else, has originated the disease. The failure to recognize and to be guided by this truth can be reasonably attributed to the faulty consensus idea which discredits known climatic results. There is probably more variation and uncertainty in mechanical appliances and ability to diagnose the incipiency of tuberculosis than pertains in any other branch of diagnosis and therapeutics. Yet the nearer we can get to the obscure or possibly undetermined etiological factors of the disease the better can we forestall the future. Every form of treatment put forward is, of course, more successful in the incipiency of tuberculosis than when the disease is advanced. Far be it from my purpose to disparage system in management and segregation of the affected poor under proved methods of treatment in well-equipped sanatoria or hospital homes, especially if located in the most favorably situated parts of our great country. But the consensus of medical opinion does not seem to recognize the inadequacy of the consumptive hospital plan near eastern cities for the great task before us. Some sanatoria for consumptives are in a measure successful, because of two fortunate circumstances, (*a*) the men in charge of them are gifted with the requisite genius and enthusiasm, and (*b*) a practically outdoor mode of life is insisted upon as a principal factor in the régime.

The preference for high altitudes to which we, who have had experience in Colorado, are wedded rests upon our personal knowledge of remarkable results. We believe these results could not or would not occur under other and low altitude conditions, except as a rarity. Yet if we were to average the whole profession's opinion on this point we would be outvoted by those who imperfectly understand and who poorly appreciate the chief factor of our climate, *viz.*, the physical effect of the rarified air upon the lungs and heart—the pulmonary air and blood circulation. That the inactive, sedative and confined life in the lowlands has its counterpart, proportioned to the rarefaction of the air, in the active, stimulating and open life of our interior altitudes, is a plain proposition which seems to be poorly understood by the majority. They have "heard tell," but they do not see it clearly that the periphery of the body is somewhat congested in high altitudes, due to the crowding of the greater amount of air breathed into the pulmonary spaces, aided by the less pressure of the atmosphere on the surface of the body. That there is always a reciprocal relation between the blood in the thorax and the air in the lungs does not seem easy to understand according to the reasoning of the advocates of the rest cure, which seems to be the favorite method with the majority of physicians. We are, or seem to be, under a spell of uncertainty, if not of fear—a practical acknowledgment of our inability to properly cope with this lethargic disease. Since the evidence of cures, by whatever method or climatic change procured, is so generally believed to be confined to the incipiency or "first stages" of the disease, let me suggest a test suited to this period. It is recommended for the consideration of those gentlemen who come in contact with large numbers of consumptives in their capacities as organizers or governors of proposed sanatoria for large cities in the East. The trial I suggest would not only be of incalculable value to these men in the management of their institutions, but the preeminent superiority of an outdoor life in our high altitudes would thus be settled.

A Suggested Outdoor Life for Incipient Consumptives.—Let these gentlemen choose or have selected by careful physical examinations one

tenth of any 500 or 1000 consumptives who came under their notice. This choice is to be based upon the fitness of these supposedly tuberculous persons for the active outdoor life proposed, and limited to those who are on the favorable side of the breaking-down period in pulmonary tuberculosis. These 50 or 100 invalids, preferably young men, are to be under the care and control of a selected physician. If he also needs this kind of life it would not greatly matter, provided he had the initiative and enthusiasm to make his mission a success. Then a hospital-tent with one or more spring-wagons, for transporting invalidated members, should also be provided; also a commissary and cook and sufficient aid to have the party live well; also a large mess-tent which should give shelter in case of storms, and freight teams for carrying same and each one's individual luggage. Other tents might also be provided, but the main idea would be to have these young men sleep out in the open nearly all the year round. In order to do this safely I would recommend each man to have an "outfit" such as the cowboys have on the large cattle ranches in the Pan Handle of Texas.[1]

Such a movable camp could outfit from one of the cities at the eastern base of the Rocky Mountains in Colorado, and start out, say in June, expecting by easy stages, ten to twenty-five miles a day when on the move, and by prolonged campings at desirable places, to reach some southern point, as, for instance, the south slope of the mountains north of Tucson, Arizona, by the first of December. Here a winter camp for three or four months might be provided with added provisions, perhaps temporary cabins, to meet the season's requirements. After this a return north by a new route could be undertaken, including unfrequented and interesting sections of western Colorado, with the object of disbanding, say in Denver or thereabouts, the following October or November. Now, under a right personal and financial organization, and a careful and conscientious choice of invalids to make up such a party of 50 to 100, I believe the results would be better than could be produced by any other at present known system or method of treatment. From the workings of such a plan it would not be difficult to conceive how changes could be made, so that it would be possible to include the care of the more seriously ill, even to the extent of having nurses along. Again, permanent camps or ranches might be established in connection with gardening, cattle- and sheep-raising. For instance, three camps five to fifteen miles from each other might be established at different elevations to suit the winter, spring and fall, and midsummer seasons; the tents with board floors being moved from one to the other. Thus, an elevation of two to four thousand feet higher in summer than in winter could be secured. Such places, having the additional advantage of fine exposure and good water, could be found in New Mexico and Arizona, where considerable tracts of land could probably be bought very reasonably for this purpose, but these suggestions are diversions from the main object of this paper.

2. The other difficulty we have to contend with in eradicating tuberculosis is the fact of the consensus of judgment among medical men hovering so closely around the germ cause that the predisposing conditions (without which the disease could not exist) go undetected and the greatest possible success cannot be obtained. In my paper upon "The Degenerative Results of Deficient Ventilation,"[1] read at the last meeting of the American Climatological Association, I have so fully worked out the proof that we as a people are living upon a deficient ventilation curve, and that this defect in our civilization is at the bottom of our prevalent tissue degeneration and tuberculous tendency, that I may be pardoned for referring thereto for the detailed argument. The conclusion therein reached was that the healthful respirability of the air depends upon its not having been previously breathed or shut off from the revivifying influence of the sun. In other words, that the electrifying, purifying and motion-producing influence of the sun cannot be shut out from the air we breathe without a resultant vitiating effect upon the blood and tissues, in the lungs especially. Thus, the air is rendered unfit for respiration, and here is the main source of the dyscrasia or degeneration which makes the destructive activity of the germ possible. Therefore this prime evil of our civilization, the faulty construction and deficient ventilation of our animal as well as our human abodes, must enter into our calculation for the successful prevention or eradication of this disease. The necessity for this reform forces to the front the educational needs of a people so ignorant and careless, so rooted to evil habits of living, that they cannot see that there is anything wrong in our "civilized" mode of life. The need of legislation is also made plain to the end that the crowding of people into large cities may be better controlled. Legislation is needed also in order that in all new buildings, to be constructed hereafter, a more generous allotment of space may be provided per human inhabitant

[1] A "tarpaulin," which is a piece of heavy 20-ounce duck or tent cloth, 7 ft. wide and 17 ft. long; three or four warm woolen double blankets, or two blankets and two comforters ("Suggins"); a "slicker," a long rubber-cloth overcoat, cowboy hat, boots, etc.; if they can afford it each one should have his own saddle-pony, saddle and accoutrements; a half dozen rifles; a half dozen shotguns and a dozen fishing-rods, together with other accompaniments for outdoor sports and games could be added. This sleeping on the ground can be done very comfortably whether one bunks alone or combines his blankets with another's to make a double bed. In either case the blankets and comforters with tarpaulin outside can be so folded as to give a comparatively soft bed in the form of a sleeping-bag. In this the camper is covered with the soft blankets next the body, the comforters and some of the blankets underneath and the tarpaulin underneath and above all. This canvas sheet is stiff enough (especially when wet) not only to shed water, but to hold its tent-shaped position when punched up above the head. This for sleeping purposes is getting down about as near to Nature as possible, and is quite feasible and possible, at least for three-fourths of the year in this dry western country.

[1] Journal of Tuberculosis, July, 1900, and Journal of the American Medical Association, July 14, 1900.

than the former average of 1000 cubic feet, obtaining in some sections, and for milch cows 400 cubic feet, roughly estimated, as the prevailing average where tuberculosis exists among them. According to investigators who have made a special study of this subject, twice the area named, and that, too, renewed every hour, is the minimum limit for healthful living.

Yet this basic argument, this causation, which apparently alone explains the great prevalence of tuberculosis alike among animals and man, is practically nullified by the consensus of opinion of the medical profession which gravitates back, "as duck to water," to the bacillary infection as the beginning and the "whole thing" of this disease. It is now "up to" tuberculosis conventions and boards of health to see and to prove how destroying the results of this disease, through disinfection and laws prohibiting or controlling expectoration, is going to eradicate or even greatly lessen the prevalence of this disease itself.

If time and a reasonable limit of this paper permitted I would add other evidence why the consensus of judgment of medical men can settle aright no investigation which has a loophole of doubt in it. The consensus is always a compromise, and a compromise is never the whole truth. The result is a practical failure so far as a conclusive solution of the question in hand is concerned. But, like the lighthouse along a rocky and uncertain coast, the attention thus drawn to the failure of the consensus judgment may lead some one else to take the right course, and the harbor of truth will eventually be reached.

THE VALUE OF THE SCHUMBURG METHOD OF PURIFICATION OF WATER FOR MILITARY PURPOSES.[1]

By JOHN H. HUDDLESTON, M.D.,
OF NEW YORK.

In March, 1897, Schumburg announced as the result of a year's laboratory work that of the many chemical disinfectants he had tested for use with drinking water bromine gave the only success. He reported that 0.06 gram of bromine kills the pathogenic bacteria in one liter of water in five minutes, and that then the bromine can be neutralized by ammonia so that a clear, tasteless and odorless water results. Resisting forms of non-pathogenic bacteria are not killed, and very hard, extremely dirty, and swamp water neutralize part of the bromine by the lime or the ammoniacal salts contained, and with such waters more bromine must be added even to the point of giving a yellowish color to the water for half a minute. The amount of bromine made by neutralizing the usual amount of bromine is only two or three grains to the liter, an amount too small to give a notable taste to the water or to effect the health of one taking it. Subsequent papers elaborated the technic of the method. Schumburg found that the bromine is best handled in a potassium bromide solution and recommended the following: ℞ Kalii bromidi, 20.00; bromi, 21.91; aquæ q. s. ad 100.00; for the bromine and for the neutralization tablets each containing sodii sulphitis, .095; sodii carb, exsic., .040; mannit q. s. Of the solution 1/5 c.c. is sufficient for one liter and is neutralized by one tablet.

Schumburg gave no experiments to support his statements but in January, 1900, Pfuhl reported in detail a series of confirming experiments. He tried water from various sources, river, pond and meadow, and added to these waters pure cultures of the cholera spirillum, the typhoid bacillus, and the staphylococcus pyogenes aureus. In certain experiments the cultures were not entirely destroyed, but in every such instance Pfuhl attributed the failure to the unusual severity of the test and to the insufficient amount of bromine employed. He noted that it is necessary for the bromine to be well mixed by stirring with the water, that the neutralizing salts should be dissolved in water freed from infection before they are added, that when the composition of the water to be tested is unknown it is safer to add sufficient bromine to give the water a yellow color for two or three minutes, and that as the bromine solution diminishes in strength very rapidly after the containing vessel is opened it is necessary after five minutes to increase the amount of solution used. The bromine method is practically useless when the water contains fecal matter in large enough amount to cause color, turbidity or foul smell; in other words, in conditions in which the water would naturally be rejected without question.

Such claims for a practical method of disinfection surely merit investigation, and a number of experiments with the bromine solution have therefore been performed by the writer. For part of these experiments cultures of the typhoid bacillus have been used from three sources; one was received from Pfeiffer in 1896 which had been continued in his laboratory for some years; one was isolated from well water in 1896, and the third was isolated from the feces of a typhoid patient in the fall of 1899. After it was found, however, that there was no difference in the way these reacted to the disinfectant, only the third culture was used. As the cholera spirillum had apparently been quite thoroughly tested by Pfuhl, and as it had appeared less resistant to bromine than the typhoid bacillus, it was not used in these experiments. Its place was taken by a culture of the bacillus coli communis. In all cases a forty-eight-hour culture was used; generally an agar culture was mixed with water and some cubic centimeters of this mixture were added to the water to be tested, but in a few instances a cubic centimeter of a bouillon culture was used instead.

[1] Read at the annual meeting of the Association of Military Surgeons of the United States, New York, 1900.

In the early experiments one cubic centimeter of the water under examination was taken for a test, added to a tube of melted agar, plated in a Petri dish, and placed in an incubator at 37° C. for forty-eight hours. In case no growth was apparent twenty-four hours more were allowed to elapse before the plate was rejected. As it was later found that bromine has but slight effect on the usual saprophytes, large numbers of colonies of spore-bearing bacilli often being found in the media, and as it was feared that a few colonies of typhoid might escape notice, recourse was had to the Hiss tube media. Stick cultures were made from the suspected water and controls from the typhoid culture employed. If the medium was not clouded at the end of twenty-four hours it was inferred that the typhoid bacillus was absent. In a few instances the Hiss plate medium was also used. Coli plates were controlled in like manner by planting colonies and in some instances a cubic centimeter of the water in fermentation tubes. If no gas appeared it was inferred that the bacillus coli communis was certainly absent; if gas developed at least one of the colon group was probably present.

Water from three sources was used: Croton water drawn from the tap in the laboratory, Albany water taken from the Hudson River, and stagnant water taken from a pool which had been standing some weeks in a city lot in Harlem. Sterile Croton water mixed with fresh urine in varying proportions was also used for the experiments. The three waters were examined for their hardness, and it was found that the Albany water was represented by 3.9 grains of calcium carbonate to the imperial gallon, the Croton water by 7.7 grains, and the stagnant water by 11 grains. The Croton water contains .0030 parts of free ammonia and .0170 parts of albumenoid ammonia to 100,000 parts of water and the corresponding figures for the stagnant water were found to be .0298 parts of free ammonia and .0183 parts of albumenoid ammonia. In other words, the stagnant water was very hard, contained a large amount of ammonia, and would have been rejected immediately for drinking water even if it had not had in addition a notably bad odor.

The time of exposure of the water to the bromine varied in the different experiments from five to seven and a half minutes.

In the first series of 25 experiments the variants especially observed were the different cultures of typhoid and the varying amounts of bromine solution. In every case 500 c.c. of Croton water was used, and the bromine solution was so diluted that 10 c.c. of the dilution represented 1/5 c.c. of the original mixture.

In specimen No. 1 the water was filtered through porcelain; in No. 2 it was boiled and exposed; these two served as controls. Nos. 3 to 17, inclusive, were simply filtered; Nos. 18 to 25 were boiled and exposed. To all of these save Nos. 16, 17, 18, 19 and 20, in which bacillus coli communis was used, typhoid bacilli derived from three sources were added. To Nos. 7 to 25 bromine solution in amounts varying from 1/10 to 1/5 c.c. was added. They were then all plated on agar with the following results. Those samples of filtered water and of boiled and exposed water to which no bromine had been added showed the presence of innumerable colonies of the organism planted. The rest of the filtered water to which the bromine had been added showed no growths; in all of the specimens of boiled and exposed water, notwithstanding the addition of the bromine, a few saprophytes grew, but no colonies of either typhoid or coli were found.

It was inferred that none of the cultures of typhoid employed offered unusual resistance and that for ordinary drinking water the minimum amount of bromine solution proposed by Schumburg is sufficient to disinfect typhoid and coli while the ordinary air bacteria may be much more resistant.

In the second series other waters were used and the bromine solution was weaker. The solution had been kept for some time in a glass stoppered bottle, but the odor of bromine showed that some had escaped, though unfortunately no analysis was made to determine the loss. As before the bromine was diluted so that 10 c.c. were the equivalent of 1/5 c.c. of the original.

NOTE.—S—saprophyte; T—typhoid; C—coli.

It was apparent that a larger amount of a more dilute solution of bromine is an efficient germicide; and it was clear that some means must be adopted to determine positively the presence or absence of a few colonies of typhoid and coli. In the next series, therefore, the Hiss tube media for the determination of typhoid and fermentation tubes for the determination of coli were adopted. The bromine solution was diluted so that 50 c.c. were the equivalent of 1/5 c.c. of the original.

The Hiss media and the fermentation tubes proved satisfactory means of determining the test cultures, the only doubt arising in No. 14, in which neither was used, and it was shown that sufficient bromine could prevent growth of even the saprophytes in the stagnant water. A series of experiments was then executed to learn the amount of urine contamination necessary to make the bromine method unreliable, and fresh urine was added to sterile Croton water in the proportions of 2, 5, 10 and 40 per cent. These mixtures of urine were then infected with typhoid and coli, and exposed to varying amounts of the same bromine solution as before.

Experiments 13 to 17 inclusive were further controlled by adding 1 c.c. of the water to Hiss plate media and examining the resulting plate microscopically, and even with that considerable amount of water no typhoid colonies were discovered. The colon bacillus proved somewhat more resisting than typhoid, but it was clear that this method of disinfection is perfectly applicable

Two controlled experiments were made with larger amounts of water and undiluted bromine solution and the results were the same as with smaller amounts.

To learn something of the effect of the treatment on the taste of water a series of glasses was prepared with Croton water, and water treated with amounts of the bromine solution and neutralizer varying from the normal amount proposed by Schumburg to five times that amount, and this series was tasted by six persons with the result that some of the series tasted a little either "salty" or "earthy" or, as several said, like "stale Congress" or Vichy.

The experiments performed, therefore, have given results quite in accord with those of Schumburg and Pfuhl. The failures have emphasized some of the limitations of the method without discrediting it, and to one having in mind the typhoid bacillus as the one the destruction of which is particularly desirable the results are most encouraging. The method is not one which may be expected to make cesspools or even puddles drinkable, though it was shown that if sufficient bromine is added it is possible to make even the stagnant water under experiment sterile. That water which has become infected with typhoid, but which is otherwise good drinking water, may by this means be made a safe source of supply would seem to be demonstrated. The occasions on which just this is desirable are numerous. Schumburg suggests, as notable instances, barracks and camps in infected localities and vessels taking on water at suspected ports. As to the practicability of the method it may be said that, most important of all, it is rapid, and furthermore that the solutions are easily made and not expensive. Bromine retails at from sixty-five to seventy-five cents a pound. The solution must be kept in sealed vessels and preferably in vessels which hold just the amount to be used for the special emergency. Schumburg has devised a military pouch, like an orderly pouch, intended to serve for the preparation of a day's supply of water for a regiment of twelve hundred men. The pouch contains tubes of the bromine solution, neutralizing salts, measuring vessels and stirrers and weighs about four pounds. A sergeant requires one tube of solution and one tube of salt for his company, empties each into a liter of water, and gives 10 c.c. of the bromine water to every soldier as he files past carrying a liter of water. The soldier stirs the solution for five minutes, and then filing by again receives the proper amount of the salt solution and in two minutes more the water is fit to drink.

In conclusion I wish to express my obligation for kind advice and assistance from Drs. W. H. Park and R. J. Wilson and for chemical analyses performed by Mr. J. P. Atkinson.

A THEORY OF THE PHYSIOLOGY OF SPINAL ANESTHESIA.

By H. H. STONER, M.D.,
OF ROCK RAPIDS, IA.

Now that anesthesia of the lower half of the body by means of a solution of cocaine thrown into the lumbar division of the subarachnoidean space is claiming the attention of surgeons and obstetricians the world over, a few words as to the probable physiological process by which it is brought about may not be out of place.

The term "medullary narcosis," so often used, is misleading, inasmuch as it gives the impression that the injection is made into the substance of the cord (a procedure which would certainly be fraught with much danger), whereas the solution is thrown into the subarachnoidean cavity some distance below the termination of the spinal cord.

During fetal life the spinal cord fills the entire spinal canal from the first cervical to the last sacral vertebra. But somewhat prior to and immediately after birth the rate of growth of the vertebral column is so much greater than that of the spinal cord that the lower extremity of the latter recedes up the canal, stretching, as it were, the nerves which have already pierced the bony foramina, so that by the time the individual has obtained his growth a cavity is left behind at the bottom of the spinal canal extending from the first lumbar to the first sacral vertebra, occupied only by the elongated roots of the lumbar and sacral nerves, known as the cauda equina, and the cerebrospinal fluid. It is into this cavity that the solution is injected.

While it is true that histologists are not unanimously agreed as to the method of conduction of stimuli from one neuron to another, the consensus of opinion, I believe, is that a functional approximation is effected between the arborizing extremity of the axone of one and the dendritic processes of the other. By means of such approximation a stimulus is enabled to pass readily through the various neurons composing a nervous tract and so reach its destination. This theory assumes that the arborizing extremities of the axones of neurones are endowed with certain mobile properties which enable them to make or break their connection with their associated neu-

rones. It is claimed that an impulse upon reaching these terminal filaments sets them to vibrating, and during the oscillation they come into contact with the dendritic processes of the associated neuron and so transmit the impulse to it. That they do possess a limited power of motion can hardly be doubted, and if so, and the movement is as above indicated, the physiology of spinal anesthesia is easily explained. The storehouse of the energy of a neuron resides in its cell-body. To its reticulated meshwork is accredited its mobile qualities; therefore any interference with the internal economics of the cell must necessarily interfere with its working capacity.

The studies of Nissl, Lugaro, Brauer and many others, concerning the effects which poisons introduced into the system have upon the cytological structure of the nerve-cells, show that these bodies become profoundly modified. Thus the tigroid bodies (the stainable portion of the cell) break up and in part or wholly disappear and are replaced by a dust-like substance, evidently the detritus left after the breaking-down of the cell. Such changes, of course, are permanent. But if continued intoxication leaves in its track such permanent results, is it not rational to suppose that a temporary intoxication would for the time being expend its energy upon the same structures that suffer from a prolonged intoxication? As that part of the neuron upon which its mobile qualities depend is in part affected by toxic agents, it follows that as the result of such morbid processes its capacity for transmitting impulses from one to another would be seriously inhibited; for the gap normally existing between them could not be closed owing to the paralytic condition of the arborizing fibrils, and the means for the conduction of its impulses from one to another would be effectually cut off. That cocaine is an active poison in the sense here used, and that in some way it transiently modifies the cytological structure of the neuron, none will deny.

Just what the modification is, or where it takes place, we cannot with certainty say; but the inference is that, like all other poisons investigated, it takes place within the body of the cell and is of such a nature as to paralyze the activities of its arborizing processes. In such an event sensory stimuli would fall short of the psychic precincts and consequently no sensation would be elicited.

It is well known that the sensory tracts are composed of at least three distinct neurons, *viz.*, the peripheral, intermediary and central sensory neurons. The peripheral neuron, beginning in the sensitive surface, passes up through the cord to the medulla where its arborizing axone terminates in functional relation to the dendritic processes of the intermediary neuron; this in turn passes to the thalamus, where it has a like relation to the central neuron; this last named neuron proceeds from the thalamus to the cerebral cortex, ending there among the elements implicated in the manifestation of psychic phenomena. Now, it is clear that, if the arborizing processes of the peripheral sensory neurons from any cause become paralyzed to such a degree as to inhibit their mobile capacity and prevent their approximation with the dendritic processes of the intermediary neurons, a functional relation between the two could not be effected, consequently sensory impulses could proceed brainward no further than the meeting-place of these two neurons in the medulla, and, of course, no sensation would be aroused. This, I take it, is what occurs when a solution of cocaine is thrown into the subarachnoidean cavity. The toxic effect of the cocaine upon the working structure of the cell-body being such for the time being as to completely destroy its tonicity, the arborizing extremity of its axone therefore retracts out of functional relation to its associate, and it becomes an entity existing wholly within itself.

In what way does the poison gain access to the cell-bodies? Of course, it cannot be by direct injection or infiltration into their substance, for they are situated, outside of the canal, in the spinal ganglia. The most plausible theory is that the axones, occupying the cavity into which the solution is thrown, absorb it and transfer it by way of their vascular supply back to the cell. It is noteworthy that the neurons most profoundly affected by the solution are those that go to make up the cauda equina. A portion of the nerve here lies exposed, as it were, and floats in the cerebrospinal fluid which is impregnated with the poison. After they pierce the cord they are protected by its substance and investing membranes. That the potency of the agent should be greatest at the point of injection, where the solution for a time is strongest, is to be expected and is borne out by clinical experience; and that the solution as it becomes diluted by the spinal fluid should exercise an effect higher up in the cord should also be expected and is borne out by clinical experience. The stronger the solution injected the more pronounced are its manifestations upon nerves located higher up in the cord. That is what we should further expect. The after-effects, such as dizziness, nausea, sweating and headache are no doubt manifestations of the effects of a much-diluted solution upon the cortical neurons of the cerebral hemispheres. The effect of the diluted solution falls short of paralyzing their processes, but instead gives rise to the symptoms enumerated. These symptoms continue in diminishing degree until all the poison is eliminated from the system.

The question now arises, Why do the motor neurons escape the paralyzing effect of the solution? It would be reasonable to suppose, if the functional capacity of a sensory neuron should be inhibited by the absorption of a cocaine solution, that the motor neurons occupying a site alongside of the sensory ones should likewise share in the functional derangement. But clinical experience proves this not to be the case. The

motor neurons, the axones of which pass through the cauda equina, apparently go on performing their function of transmitting motor impulses unmindful of the presence of the toxic agent. It must not be supposed that these neurons are unaffected by the solution. The cytological structure of their cells certainly undergoes the same morbid change as do those of the sensory neurons, but, owing to the direction of the motor current and the relation of the end plates of the peripheral motor neurons to the muscle fibers, their capacity for transmitting motor stimuli to their destination in the muscle is not seriously handicapped. A motor tract, as is well known, is composed of a central and a peripheral neuron, also that the junction of the two takes place in the anterior horn of the cord; therefore the peripheral motor neuron only is affected by the toxic agent. Stimuli over the sensory tract are prevented from reaching their destination owing to paralysis and withdrawal of the arborizing extremity of the peripheral sensory neuron from contact with its associated one, but in the case of the peripheral motor neuron no such ending takes place.

These neurons terminate in end plates by anastomosis with muscle fibers, consequently they cannot retract out of functional contact with the muscle, and any impulse which reaches this neuron must expend its energy upon the muscle fiber with which it is connected. The relation of the end plate of the neuron to the muscle fiber is such that it cannot be broken. The central motor neuron arising in the cerebral cortex and ending by its arborizing extremity in functional relation to the dendrites of the peripheral one is not in any way influenced by the cocaine solution, so that motor impulses may traverse the motor tract from brain to muscle unimpeded.

Why the reflexes are abolished in the anesthetic areas is also patent. The reflex mechanism of the cord is as follows: Immediately upon entering the cord the axones of the sensory neurons divide into two branches, one ascending and the other descending. From the descending branch a collateral is given off, the arborizing extremity of which terminates in functional relation to the dendrites of the peripheral motor neuron. In the natural state of these organs a sensory stimulus upon entering the cord may take one of two directions, or it may disperse and take both.

A portion may pass up the ascending branch, and upon reaching the brain give rise to sensation, and the other portion may take the reflex route over the descending branch and its collateral to the cell of the peripheral motor neuron, in which event a reflex action is excited. Now, it goes without saying that the solution paralyzes the arborizing processes of this collateral branch as well as those of the ascending branch, and such being the case it is withdrawn from functional relation to the peripheral motor neuron and reflex activities are thereby inhibited.

MEDICAL PROGRESS.

Dry Sterilized Catgut Ligatures.—J. H. Carstens (*Am. Jour. Obstetrics*, Nov., 1900) says that he has tried all the different kinds of catgut ligatures and has always found something wrong. The greatest objection he found to all these ligatures was that they lasted too long. After many experiments the writer prepared a dry sterilized catgut ligature as follows: The catgut is put into ether for a few days to remove all fat, and then cut into 18-inch lengths. Three 18-inch lengths are wrapped together in tissue paper. This is put into a small envelope, which is then sealed and placed in the Boerckman sterilizer and subjected to dry heat for three hours. The thermometer in the apparatus will show that the heat is at least at 300° F. After three hours the heat is shut off and the ligatures remain undisturbed in the apparatus for from twelve to eighteen hours to give opportunity for any spores to develop. Then the heat is again turned on for three hours at 300° F. The ligatures are now sterile. They are in an envelope and can be carried in a satchel. When a ligature is desired the end of the envelope can be torn off, the ligatures wrapped in tissue paper dropped into alcohol, the tissue paper removed, and the ligature threaded and used. These ligatures are never slippery, the knot never slips, they soften and liquefy and are absorbed in a week or ten days if not contaminated. Repeated tests have always found these ligatures sterile. The points Carstens makes about the dry sterilized catgut ligatures are: (1) All buried sutures ought to be absorbable. (2) All absorbable ligatures must be absolutely sterile. (3) Chemicalized sutures are no more sterile than plain sutures. (4) A suture that is chemicalized is harder and remains longer in the tissues. (5) This latter is no advantage, but a disadvantage. If in any case it is desirable that a suture should remain longer, use dry sterilized kangaroo tendon.

Clinical Characters of Tremor.—Tremor is often an important diagnostic point in arriving at a proper conclusion in regard to the nature of disease and is so easily observable that its value should be appreciated. R. F. Williamson (*Med. Chron.*, Oct., 1900) reviews the peculiarities of the common forms and says that it is important to note what part is affected, whether the tremor persists when the limb is at rest and whether it is increased, diminished, or arrested by voluntary movements. The influence of mental emotions, etc., should also be tested. Tremor is an important symptom of paralysis agitans. It is unilateral at first and then becomes bilateral. The movements are usually most marked in the thumb and finger, causing a flexion and extension, or pill-rolling movement. It is usually most marked during repose and either ceases entirely or is greatly diminished by voluntary movements. The handwriting is therefore affected later. Other characteristics of the disease appear, as the pe-

culiar attitude of the body, the muscular inertia and rigidity, the fixed facial expression, etc. In disseminated sclerosis tremor appears only on voluntary movement, and hence is called intention tremor. It consists of coarse, jerky oscillations, brought out more distinctly by efforts to perform fine, slow actions. Attempts to drink a glass of water frequently give typical results. The handwriting is affected early and the letters are extremely jerky and irregular. Muscles of the whole arm become involved and sometimes those of the head or the entire body. In alcoholism the tremor occurs, not only in the hands, but in the face, lips, tongue and perhaps the legs. The tremor is fine, rapid, not confined to the hands or fingers, increased by voluntary movement and often chiefly lateral when the arm is extended. In writing the letters are wavy and irregular, but not so marked as in disseminated sclerosis. The senile, asthenic, simple and hysterical tremors usually occur during repose, but are much greater during voluntary movement. The clinical history of the case assists diagnosis materially.

Suprarenal Gland in Hay-Fever.—Contrary to the favorable results Solis-Cohen obtained in hay-fever from the administration of suprarenal gland by the mouth, Lewis S. Somers (*Phila. Med. Jour.*, Dec. 8, 1900) reports 21 cases in which the results were not entirely satisfactory. These patients varied in age from seventeen to fifty-six years, and received the suprarenal extract exclusively for periods varying from one to six weeks each. Ten of the patients were obliged to discontinue the suprarenal tablets after a week's trial because of disagreeable symptoms, while 7 of them used them continuously for six weeks. Tablets of 5 grains each were found to be the best form in which to administer the drug, as they did not produce as much nausea as the glycerin solution did. A five-grain tablet was given every two hours except in those cases in which it produced disagreeable symptoms, when the same dose was given every four hours, from 15 to 75 grains being taken daily. The nasal symptoms were but slightly affected, the sneezing attacks were apparently less frequent, but no less severe than formerly. The nasal stenosis was favorably affected in about one half of the cases, the turbinals being diminished in size. The pruritis of the chin and buccal mucous membrane was less when the tablets were dissolved in the mouth, but not when they were swallowed. All those patients who had had asthmatic symptoms, during the hay-fever season only, were unfavorably influenced. The paroxysms became more frequent and more severe while the suprarenal tablets were being taken. In 5 cases which had never had asthmatic attacks they appeared while the drug was being taken and disappeared when it was withdrawn. The effect of the drug was more satisfactory when the tablets were allowed to dissolve upon the tongue than when they were swallowed. In the latter case there were little or no appreciable results obtained. The chief disagreeable symptoms noted were nausea, a sense of chest-constriction, and the development of asthma or the augmentation of the paroxysm when it already existed. Somers does not think that the favorable results obtained were of sufficient magnitude to recommend its use for this purpose. Locally, he considers suprarenal extract of great service, but, internally, he considers it of little or no use in the treatment of hay-fever either with or without conjoined treatment.

Abortive Treatment in Gonorrhea.—C. Kopp (*Münch. med. Woch.*, Nov. 27, 1900) recommends that after every suspected coitus, the meatus and fossa navicularis of the urethra be thoroughly rubbed with a small piece of cotton on a sound and that a few drops of a two-percent. solution of silver nitrate or of twenty-percent. protargol-glycerin be brushed over the same area. The inflammatory reaction which follows is but slight and lasts only a few hours. He has been able to abort the disease twelve hours after the infection.

Pleomorphism in Bacteria.—E. Schwalbe (*Münch. med. Woch.*, Nov. 20, 1900) discusses the interesting question whether it is possible, by different methods of culturing, to change one variety of bacteria into another. The term pleomorphism has been wrongly applied to such bacteria which assume different forms during their cycle of development; thus, the bacillus subtilis at different times appears as rods and again as threads. An illustration of the term, in its more proper restriction, is afforded by the tubercle bacillus, or more properly, fungus. It has been possible by inoculating it into cold-blooded animals to considerably alter its morphological and biological characteristics so that really a new variety results. It has been known for some time that most pathogenic germs may be rendered avirulent by growing them on artificial media and more recently it has been found that a certain chromogenous bacterium, the staphylococcus pyogenes aureus, can produce colors of different shades after proper manipulation. While artificial cultivation may thus result in the formation of different sub-classes, the evidence that one distinct class may be converted into another is not forthcoming.

Causes of Insanity.—On account of the inability to discover organic changes in the brains of so many insane persons and on account of the indefinite and varied character of the structural lesions when they are found, innumerable pathological conditions in other portions of the body have been suggested as of sufficient influence to cause the abnormal manifestations of the brain. M. D. Jones (*Med. Rec.*, Dec. 15, 1900) discusses at considerable length and analyzes a number of cases to show the relation of the sexual function to insanity. She believes that since ovulation and generation are normal functions, disease of

the genital organs in woman may be the source of great irritation and may even cause such exhaustion and prostration as to produce extreme nervousness and even mania and insanity, but that these abnormal mental conditions can occur only in those who have some neurosis, brain lesion or inherited tendency thereto. As causes of insanity she lays especial stress upon the influence of heredity which is generally acknowledged as an efficient factor. The abuse of alcohol is another prolific cause and has been found to be largely responsible for at least twenty-five per cent of cases admitted to certain hospitals. Its deleterious effects are exerted not only upon the person using it, but also upon the mental and physical development of the offspring, especially if begotten while the parent is in a state of drunken stupor. The condition of other organs of the body, the stomach, intestines, the circulatory and respiratory systems, all have their influence, and, perhaps, as much so as the genital organs, in causing insanity among those who are mentally weak or are predisposed to mental abnormalities.

THERAPEUTIC HINTS.

Ovarian Pain.—An excellent combination is

℞ Potass. bromid..... 1.0 (gr. xv)
Chloral hydrat..... 0.8 (gr. xij)

given at intervals of four hours.—*Macnaughton-Jones.*

Muscular Rheumatism.—Severe and acute forms, writes J. M. Anders, require anodyne and hot applications, and opiates. Hot fomentations, the Turkish bath, hot-water bag, hot-water sponging, or dry heat by bags filled with salt or hops, promote comfort, and, if begun early, may abort the attack. The affected muscles, especially in torticollis, may be covered with flannel and a warm flatiron passed over for a few minutes. For lumbago, sterilized needles, 3 or 4 inches long, are inserted at the seat of pain, and withdrawn after five or ten minutes. Blisters have not proven of value. In subacute and obstinate cases a twenty-per-cent. salicylic-acid ointment may give good results. Active friction with anodyne and stimulating liniments, massage, and electricity are worthy of trial. In all cases antirheumatic remedies are to be employed, and, if chronic, potassium iodide guaiacum, and small doses of arsenic may be added. The nutrition and general health must also be looked after.—*Practice of Medicine.*

Acute Pneumonia.—The severe pain at the onset, write Fowler and Godlee, is probably due to the stretching of the inflamed pleura by the engorged lung. It may be relieved by an ice-bag, but leeches or a large linseed poultice are preferable. The poultices should be changed every two or three hours. In lieu of these the affected side may be covered with a layer of cotton-wool heated at the fire and sprinkled with a stimulating liniment. When the poultices are discontinued a cotton-wool jacket should be worn. Rest must be absolute, and at the onset will be promoted by morphine, 0.01-0.015 (gr. 1/6-¼), repeated once if necessary. Later in the disease morphine is dangerous. Calomel, 0.2 (gr. iij), should be given early, and followed by an aperient. The functions of the skin must be maintained by citrate of potash, acetate of ammonia, and quinine, 0.06-0.2 (gr. j-iij), every four hours. Aconite and tartar emetic are depressant and harmful. The diet may consist of two pints of milk and a pint of beef-tea in twenty-four hours. Diminish this quantity if the stomach is at all distended. Sponging the surface of the body with water at 80° F. is grateful to the patient, lowers temperature, relieves restlessness, and promotes sleep, yet it has little, if any, effect on the course of the disease. For temperatures of 105.8° F. or over, the ice-cradle or ice-pack may be used. Oxygen, digitalis, and ammonium carbonate must be employed early to ward off cardiac failure, and when this supervenes, brandy, even up to twenty ounces a day, should be given. The patient must be carefully watched, for harm may be done by over-stimulation of a weak heart. Strychnine and caffeine are valuable heart tonics. Nothing is so useful as morphine for violent delirium or hiccough. Cyanosis, epigastric pulsation, prominence of the jugular veins and a small, irregular pulse are indications for venesection. Balfour advocates

Chloral ..... 0.7 (gr. x)
Infus. digital..... 15.0 (℥ ss)

every four hours during the period of pyrexia. For delayed resolution the syrup of iodide of iron may be given with quinine.—*Diseases of the Lungs.*

Treatment of Vulvar Papillomata.— Each papilloma can be separately cured in from 5 to 8 hours. Use this solution:

Acid. salicylic ..... 2.0 (grs. xxx)
Collodion flexible .... 5.0 (grs. lxxv)

Apply some drops of this solution on 8 or 10 papillomata at the same treatment. The next day apply some to eight or ten others and repeat the application to the first group. Continue this treatment until they all disappear.

Or, paint with a brush dipped in:

Acid. acetic ..... 30.0 (℥viiss)
Acid. salicylic ..... 2.0 (grs. xxx)

After each cauterization, powder with this mixture:

Tannin .... 15.0 (℥iv)
Salol ..... 10.0 (℥iiss)
Bismuth subnitrate ..... 20.0 (℥v)

If the papillomata are very large, remove with a sharp curette and then cauterize with the thermo- or galvanocautery.— *Jour. de Méd. de Paris.*

Urethral Chills.—To ward off chills following internal urethrotomy or the use of sounds:

℞ Morph. sulph.... 006 gm. (gr. 1/10)
Tinct. aconiti.... .15 cc (♏ ij)
Ol gaulther.....1.0 cc. (♏ xv)

Pharyngitis.—Inflammation of the pharynx and tonsils, writes J. V. Shoemaker, is lessened by belladonna, and this may well be combined as follows:

℞ Potass. chlorat..... 0.5 (gr. lxxv)
Tr. aconiti..... 1.0 (♏ xv)
Tr. belladonnæ..... 2.0 (♏ xxx)
Ac. hydrochlor. dil... 6.0 (ʒ iss)
Infus. rhois glabræ
q. s.....ad. 120.0 (ʒ iv)
Sig.: Tablespoonful every third hour.
—*Materia Medica and Therapeutics.*

Catarrhal Jaundice.—

℞ Mangani oxid..... 2.0 (ʒ ss)
Res. podophylli..... 0.13 (gr. ij)
Ext. belladon..... 0.065 (gr. j)
M. ft. capsul No. X. Sig.: One three or four times a day.
—*Shoemaker.*

Obstinate Constipation.—To overcome fecal impaction and in the constipation of lead poisoning give:

℞ Magnes sulph..... 8.0 (ʒ ij)
Morph. sulph..... 0.065 (gr. j)
Aq. menth. piper.....ad. 90.0 (ʒ iij)
Sig.: A tablespoonful every two hours.
—*Shoemaker.*

Régime in Rest Cure.—7.30 A. M.—Glass of milk, hot or cold, predigested, boiled or raw. 8 A. M.—Sponge patient with tepid water, or alternate hot and cold water, the body being well wrapped in a blanket except the part being bathed. Dry with a rough towel with friction. 8.30 A. M.—Boiled, poached, or scrambled eggs, milk toast, water toast, or finely cut mutton-chop or chicken. 10 A. M.—Massage for half to one hour. 11 A. M.—Glass of milk, milk-punch, or egg-nogg. 12 M.—Read for one hour. 1 P. M.—Small piece of steak, rare roast beef, consommé soup, mutton broth, and an easily-digested and well-cooked vegetable. 3 P. M.—Electricity to individual muscles. 4.30 P. M.—Glass of milk, milk-punch, or egg-nogg. 6.30 P. M.—Buttered toast, milk, curds and whey, or plain custard, no tea or coffee. 9.30 P. M.—Glass of milk or milk-punch.—*Hare in "Practical Therapeutics."*

Acute Laryngitis.—Early in attack, says G. M. Lefferts, apply ice bag or Leiter's coil to neck, and swallow ice. If this does not abort, apply warm compress, give hot demulcent drinks and warm milk and seltzer, and frequent inhalations of steam medicated with tinct. benzoin comp. or paregoric, 4.0 to 500.0 (ʒj-0j) of water. As the inflammation subsides insufflate with equal parts of starch and tannin or alum, or use a spray of zinc sulphate, 1.0 to 30.0 (gr. xv-ʒj), or the tincture of iron chloride, 2.0 to 30.0 (ʒ ss-ʒ j). Continue this for at least two weeks. Keep nasopharynx clean by sedative and astringent sprays, give aconite internally, and compressed tablets of ammon. chlorid, chlorate of potash, cubebs, etc. At the outset a laxative and expectorants may be given, and aconite, belladonna, or codeine. If edema supervenes either scarification, intubation, or tracheotomy is required.

Chronic Rheumatism.—Liniments are of value because they relieve pain and do good to the parts either through their own virtues or on account of the rubbing, and because they give the patient something to do or have done. Useful formulæ are:

℞ Tinct. aconiti..... 8.0 (ʒ ij)
Tinct. opii.....30.0 (ʒ j)
Ol. terebinth.....30.0-60.0 (ʒ j-ij)
Lin. saponis q. s.....ad 240.0 (ʒ viij)
Sig.: Poison! Use three times a day.
or
℞ Aq. ammon. fort.....15.0 (ʒ ss)
Ol. cajuputi..... 4.0 (ʒ j)
Tr. belladon.....30.0-60.0 (ʒ j-ij)
Lin, camphoræ. q. s...ad. 240.0 (ʒ vij)
Sig.: Apply frequently.
—*Hare in "Practical Therapeutics."*

Pruritus.—The internal treatment, writes Geo. T. Jackson, consists of cod-liver oil, iron, and good diet, with tincture of cannabis, 0.7-2.0 (♏ x-xxx), t. i. d. for a ten-year-old child, or two per cent. pilocarpine solution, 1.0 (♏ xv) once a day, the patient remaining in bed and covered with blankets until he sweats for two or three hours. Carbolic acid 1.0 (♏ xv) a day, bromide of potash, phenacetin, and antipyrine are also of value. For local treatment a 2 to 5 per cent. solution of naphtol may be rubbed in every night and a bath with naphtol-sulphur soap taken each second night. Sulphur, tar, carbolic, salicylic or boric acid ointments have their advocates. Baths followed by inunctions of sweet oil, cod-liver oil, tar oil, or lard, or baths alone of alum, soda, or corrosive sublimate are often useful. The affected parts may be wrapped with good effect in some protective dressing, such as rubber sheeting or cotton.—*"Diseases of the Skin."*

Furuncles of the Ear.—If the auditory canal be filled or unclean, advises A. Rupp, it must be syringed out with a 2 to 5 per cent. carbolic solution followed by sodium bicarbonate solution as hot as can be borne. Dry the canal with absorbent cotton, and if the membrana tympani is intact fill with:

℞ Hydrarg. bichlor..... 0.3 (gr. v)
Glycerin .....
Alcohol .....aa. 30.0 (ʒ j)

which is to remain in some minutes and then be drained off. Close canal lightly with borated or salicylated absorbent cotton. If the membrana is deficient fill canal with powdered boric acid, and close as before. When furuncles are at the inner end of the canal near the membrana, a leech or two in front of the tragus affords much relief. Boils should be incised only where pus has formed and has no outlet.—*G. T. Jackson's "Diseases of the Skin."*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

ABSENT TREATMENT AND DEATH CERTIFICATES.

NEW YORK CITY for the past few weeks has been the scene of a most interesting spectacle. Publicly and in high places the community has been assured that there is no such thing as sickness; that Christian Science can cure all that the human mind understands to be disease and that all that is necessary to eradicate tuberculosis, cancer, smallpox, typhoid fever, or even to be able to raise the dead, is to become a *healer* and *think about it.*

All of this we regret to say we have heard before; and the medical profession has been unable to make much headway against the present wave of ignorant fanaticism that is so profitable to the high priests thereof; but there is one phase recently brought out that can be remedied and we commend it most heartily to the Health Board and the County Medical Society for investigation.

It appears from the testimony, which is being so ably brought out by the learned counsel in the Brush will case, that patients of Christian Scientists do occasionally have human manifestations such as scarlet fever, tuberculosis, etc., and that they do die. We learn that cases of contagious diseases are not reported to the Board of Health and that death certificates are being granted by a Dr. Pease, a so-called legal practitioner, without the formality of seeing the patient.

Absent treatment, even to the point of granting death certificates, is too much, and we register a protest.

BELLEVUE HOSPITAL REFORM.

A FEW weeks ago when the revision of the charter of the City of New York was being discussed, we approved unreservedly of the changes outlined by the Committee on Revision in which it was proposed to vest the governorship of Bellevue Hospital in a board of unsalaried trustees.

We refrained from specifying what almost every medical man in the city knew, that the nature of the abuses and slack management were due not to any one person's management, but to the system.

The daily papers have rather ruthlessly torn the veil of charity which we refrained from disturbing from one or two scandals of the hospital; so that we may perhaps feel less delicacy than we did before in expressing our opinions.

We note that these scandals are of a very popular nature, such as arouse a Sunday afternoon indignation on the part of the readers of bright literature, which indignation is usually satisfied by learning that the brutal nurses were suspended or dismissed.

The energetic investigations that the Charity Commissioner has been making are very commendable; but what will happen when Mr. Keller is succeeded by a less enterprising man? And how does it happen, if we may ask, that these abuses have just been brought to light? Moreover, there are less spectacular abuses that are not so easily disposed of; abuses that deal with food, cleanliness, clothing, and sleeping quarters; abuses that cannot be judged by the mouth of two witnesses, but that are the outcome of political jobbery.

Undoubtedly the argument is true that many of the alcoholics at Bellevue are better off than in the gutter, and many of the patients are better fed than they ever were in their own homes. But there are others whose standard is not so low, and when we are considering the standard of New York's greatest public hospital, we do not judge by the requirements of a tramp; but by the city's ability to provide for its poor. And this is just the point; the city has provided amply; but the provision has been badly administered, and it is high time to change.

NEW METHODS IN CHARITY, AND AT LESS COST.

At a meeting of the First New York State Conference of Charities and Correction, held in the Senate Chamber of the Capitol at Albany, November 21, 1900, the Chairman of the Committee on the Mentally Defective, Dr. Wm. P. Spratling, Superintendent of the Craig Colony for Epileptics, said, among other things:

"Mr. Roberts, State Comptroller in 1896, said that the State that year had the sum of $19,323,245 invested in permanent buildings and improvements for the care of the insane and other defective and dependent beings. He also stated that the State was spending annually $5,200,000 to maintain the people in these buildings." The author of the paper offered the following suggestions by which the first cost of preparing to take care of this vast army might be lessened, and the cost of their maintenance might also be reduced: (1) Prevention; (2) maintenance; (3) construction; (4) education of a suitable kind.

For prevention, laws should be enacted, if possible, by which the marriage and intermarriage of defective and dependent epileptics and other weak-minded persons might be prohibited. It is a question whether or not the Constitution of the State would admit of this being done; at any rate, there can be no harm in making an effort. We are certain that if the State had an effective law of this kind, and honestly carried it out, very much would be done toward cutting off a blasted progeny.

The word maintenance is largely an elastic term. Maintenance should not mean education or attendance upon these defectives by nurses and physicians especially trained for the purpose, but should mean providing them with food, lodging and ordinary care.

It is a well-known fact that a very large number of the insane are absolutely incurable. Then why go on building vast architectural piles in which these people are kept? We suspect that the reason why this has been the practice to this time has been to meet a local pride. The residents of the community like to point to one of these magnificent structures and say, "We did it; we are responsible for that magnificent institution." It would be much better if they could say, "There stands a model State institution; cheaply, but effectively built, and one that meets every purpose to which it is put."

Dr. Spratling also urged the construction of small hospitals in connection with the great cities, where the acutely insane could be taken just as soon as they become mentally unsound. These hospitals should be small; they should be presided over by the best brains that money can buy; they should be centers for teaching. Build dormitories in connection with them, if necessary, and let the physicians go there and live and acquire a real knowledge of insanity. Too many physicians, we fear, have but little knowledge of insanity, epilepsy, and the allied neuroses. The place to treat insanity is really at the patient's home when the disease first appears. But how can that be done unless the physician have a good knowledge of the disease he is treating?

The author also thinks that far less money should be spent on about one-fourth of the chronic insane. These people should be colonized in vast agricultural communities, and put at all sorts of trades, farming and gardening. They should lead a healthy outdoor life. The idea should be to spend far less money on this class and far more money on the acutely insane, who would be in the small hospitals. We think that the State should, and will yet, come to this. It will have to if it does its full duty by the people it has undertaken to protect.

The author of the paper thinks that the word "custody" should be abolished and the word treatment substituted instead. Custody means mere care, *i. e.*, the bathing, dressing and feeding of patients. Every patient should be under good care and treatment, for no human being can be dogmatic enough to say what case is curable and what is not. Proper education of a general kind for the State's wards has never been put into practice. Many of them must be under State care as long as they live. Put them in school; teach them simple things, things that they can use as State charges and that will help to reduce the cost of their maintenance.

Instead of building vast architectural piles, small homes should be built. Instead of putting from $550 to $3000 in a building per bed, put in $300 or $400. That is ample; that will build the very best kind of buildings, buildings that will stand for a generation.

To sum up, the following, the author thinks, is required: (1) Prevent insanity, epilepsy, imbecility, idiocy, feeblemindedness, as far as possible, by forbidding afflicted persons to marry or intermarry. (2) Maintain *at less cost* the cases that are chronic and incurable, and maintain, under proper treatment, *at greater cost, to stimulate recovery*, those that probably can be

cured. (3) Build less expensive structures in which defective and dependent State charges shall live. (4) Give those that ought to have it an education that they can use, either in the institution that cares for them, that the cost of their maintenance may be lessened, or that they may use in the outer world when they leave the institution, when the State has done its work well and turned them back into the great business current as nearly normal men and women as science and art can recreate them.

Some one in Scotland has estimated that the average man, striking the balance between the banker and the pauper, is worth $400 a year to the community in which he lives. The distinguished Lunacy Commission in the State of New York has ascertained that the sum of $6000 is spent, first and last, upon every individual committed to a State Hospital for the Insane. Surely it does not require a very acute mind to see on which side the burden of cost presses hardest and longest.

ECHOES AND NEWS.

NEW YORK.

Academy of Medicine's New Officers.—The New York Academy of Medicine held its annual election of officers last week. The officers elected were: President, Dr. Robert F. Weir; Vice-President, Dr. Charles L. Dana; Recording Secretary, Dr. John H. Huddleston; Trustee, Dr. Alexander A. Smith; Corresponding Secretary, Dr. Louis F. Bishop; Member of the Committee on Admissions, Dr. John Van Doren Young; Member of the Committee on Library, Dr. Charles L. Fisk.

An Institution to Watch—The School of Health, with principal offices in New York, was incorporated December 19th, to found and carry on a School of Health in New York, with branches in other cities, for mental and physical culture, instructions in sanitary laws, the laws of heredity, the evil effects of tobacco, alcohol and morphine upon the human system, and the chemistry of cooking, food values and their adulterations. The directors are: Dr. Ella A. Jennings, Dr. Egbert Guernsey, John J. Plunkett, Sylvester M. Weimer of New York; George Donaldson, Cliff Side, N. J., and Mrs. E. C. Hazard of Shrewsbury, N. J.

Bequest to Eye and Ear Infirmary.—William C. Schermerhorn, Second Vice-President of the New York Eye and Ear Infirmary, at Second Avenue and Thirteenth Street, presented that institution with $75,000 on Thursday, December 20th. The money is to be expended in the construction of a pavilion for patients having disease of the ear.

New Charter and Health Officers.—Members of the Charter Revision Commission say that the fears which have been expressed by residents of outlying boroughs regarding the convenience of the new Health Board provisions are based on a misapprehension of the charter. They say it gives the Health Commissioner full power to establish as many branch offices as are required.

A Subject for Investigation.—Commissioner Keller is still hard at work investigating Bellevue. Last week he received a verbal complaint from an alienist of this city that there was a "combination" between two of the insanity experts who examine all supposed lunatics brought to Bellevue, whereby rich patients were turned over to the physicians' private practice and were also recommended to certain sanitariums.

Obituary.—Dr. John E. Losee, one of the oldest and most prominent physicians in northern Dutchess County, died Saturday at his home in Upper Red Hook, aged seventy-four years. He had practised his profession for forty-seven years in that locality. He was born in Saratoga County, N. Y., and graduated from the Albany Medical College in 1852. After several months in the old New York Hospital in 1853 he entered active practice in Upper Red Hook.

Dr. Frederick Osborn Lloyd died last week at Hamilton, N. Y., of heart disease. He was at one time attached to the staff of the Presbyterian Hospital in this city and practised medicine here. His widow and a son survive him.

Dr. John Henry Fruitnight died last week at his home, 161 West Fifty-seventh Street, aged forty-nine years. He was graduated from the College of the City of New York in 1872 and from the Bellevue Hospital Medical College three years later. Dr. Fruitnight's work as a specialist in the diseases of children was highly appreciated by his professional confrères.

Dr. Charles Sabin Taft, one of the surgeons who attended President Lincoln immediately after the President was shot in Ford's Theater, died last week at his home, 39 South Seventh Avenue, Mount Vernon, of cancer of the throat.

Medical Society of the State of New York.—The preliminary program of the ninety-fifth annual meeting of this Society is just to hand. The following papers will be presented: "Recent Progress in the Treatment of Pneumonia," by James King Crook, New York; "Congenital Dislocation of the Shoulder with Report of Cases," by Daniel W. Marston, New York; "Appendicitis and Menstrual Irregularities," by A. L. Beahan, Canandaigua; "Small Hospitals and Their Administration," by Louis Nott Lanehart, Hempstead; "The Necessity of Greater Conservatism in the Use of Vasodilators, in Certain Cases of Cardiovascular Disease," by Louis Faugeres Bishop, New York; "Hernia of the Urinary Bladder," by William S. Cheesman, Auburn; "Treatment of Prostatic Hypertrophy," by Ramon Guiteras, New York; "The Medical Society

of the State of New York: Its Past and Future," by Albert Vander Veer, Albany; "What is Rodent Ulcer?" by John A. Fordyce, New York; "Noma of the Genitalia," by Andrew McFarlane, Albany; "Esophoria or Latent Squint," by Francis Valk, New York; "Changes in the Crystalline Lens During Accommodation," by Lucien Howe, Buffalo; "Treatment of Chronic Purulent Otitis Media," by James F. McKernon, New York; "Tuberculosis of the Iris," by W. F. Mittendorf, New York; "Can Interstital Keratitis Be Prevented in the Offspring of Syphilitic Parents?" by Peter A. Callan, New York; "Operations for Deformities Following Pott's Fracture," by W. O. Plimpton, New York; "Indications for Operations Upon the Mastoid," by Wendell C. Phillips, New York; "Indications and Limitations of the Vaginal Route of Attack in Pelvic Diseases in Women," by J. Riddle Goffe, New York; "What Complications of Pregnancy, Labor, or Puerperium Justify Abdominal Section?" by William Warren Potter, Buffalo; "The Treatment of Persistent Suprapubic Fistula Resulting after Ovariotomy," by Willy Meyer, New York; "Results Following the Cure of Chronic Defects on the Vesical Function," by Eugene Fuller, New York; "Ectopic Pregnancy, Primary Rupture, the Opportune Time for making Diagnosis," by George McNaughton, Brooklyn; "An X-Ray Study of the Causes of Disability Following Fractures Involving the Elbow Joint," by Samuel Lloyd, New York; "Contributions to Abdominal Surgery," by James E. Keely, New York; "Loose Cartilage in the Knee-Joint," by P. R. Furbeck, Gloversville; "Pus in the Peritoneal Cavity," by Robert T. Morris, New York; "The Indications for and Limitations of Spinal Cocainization in Surgery," by George R. Fowler, Brooklyn; "The Results of Nephropexy for Movable Kidney," by George M. Edebohls, New York; "Relations Between Certain Diseases of the Skin and the Menstrual Function," by L. Duncan Bulkley, New York; "Hysterical Anesthesia and Analgesia," by B. C. Loveland, Syracuse; "Deep Breathing as a Curative and Preventive Measure," by John H. Pryor, Buffalo; "Masturbational Neuroses," by William C. Krauss, Buffalo; "Arthritis Deformans," by Herman Mynter, Buffalo; "Tenosynovitis Calcarea," by Carl Beck, New York; "The Treatment of Puerperal Fever," by Herman J. Boldt, New York; "Belladonna *vs.* Scopolia," by Reynold W. Wilcox, New York; "Disinfection Within and Without the Body in Diphtheria," by M. A. Veeder, Lyons; "After-Thoughts on Diphtheria," by J. N. Love, New York; "Fatty Degeneration of the Heart," by Thomas E. Satterthwaite, New York; "Recent Experiences with Erythromelalgia," by Henry L. Elsner, Syracuse; "A Simple and Accurate Method of Substitute Infant-Feeding," by Henry Dwight Chapin, New York; "Leprosy in the Hawaiian Islands," by Charles E. Davis, Albany; "The Ponometer and its Value in Determining Arterial Tension," by Henry L. K. Shaw, Albany; "Pleuropericardial and Diaphragmatic Adhesions. Illustrated by Colored Wax Models," by D. H. Goodwillie, New York; "Differential Diagnosis in Diseases of the Spinal Cord," by E. D. Fisher, New York; "The Immunizing Effect of 'Rag Weed' in Hay-Fever," by H. Holbrook Curtis, New York.

"Contribution to Pelvic Infection in Women," by Charles A. L. Reed, Cincinnati, President American Medical Association; discussed by: J. F. W. Ross, Toronto, Ontario; L. S. McMurtry, Louisville, Ky.; W. E. B. Davis, Birmingham, Ala.; Bache McE. Emmet, New York; William M. Polk, New York; George M. Edebohls, New York; James Clifton Edgar, New York; James P. Boyd, Albany; "Report of Five Cases of Ovarian Tumors with Twisted Pedicles," by George B. Johnston, Richmond, Va.; "Surgery of the Spleen," by J. Collins Warren, Boston, Mass.; discussed by: Albert Vander Veer, Albany; Charles McBurney, New York; Robert F. Weir, New York; Robert T. Morris, New York; Thomas Roddick, Montreal, Canada; "The Pathology and Diagnosis of Intestinal Obstruction," by J. B. Murphy, Chicago, Ill.; "Inguinal Hernia," by Merville Ricketts, Cincinnati, O.; "Gastrojejunostomy in Gastrectasis," by A. H. Cordier, Kansas City, Mo.; "Toxin of the Colon Bacillus," by Victor C. Vaughn, Ann Arbor, Mich.; "The Treatment of Delirium Tremens by the Intravenous Infusion of Saline Solution," by James P. Warbasse, Brooklyn; "Tetanus Following Clean Operation: Report of Cases," by Joseph W. Bissell, New York; "The Advances in State Medicine," by M. J. Lewi, New York; "Aseptic and Antiseptic Precautions in Dental Surgery," by J. B. Ransom, Dannemora; "Report of Case of Brain Tumor; Operation; Improvement," by William M. Leszynsky, New York, and James H. Glass, Utica.

PHILADELPHIA.

Attendance at Medical Colleges.—The number of students at the various medical schools at present is as follows: Jefferson, 752; University of Pennsylvania, 566; Medico-Chirurgical, 416; Woman's Medical, 164; total, 1898. In addition there are 1224 students of dentistry and 505 students of pharmacy.

Reception to Dr. Weir.—Dr. Robert F. Weir, of Columbia University, visited this city December 19th as the guest of Dr. W. W. Keen. After being tendered a reception and dinner at the University Club, Dr. Weir operated in Dr. Keen's clinic at the Jefferson Hospital, one case being a nephrectomy for sarcoma of the kidney.

Graduation of Nurses.—A class of seven nurses received diplomas from the Jefferson Hospital training school December 20th. Dr. E. P. Davis, in presenting the medal of honor, stated that the course of three years was none too long and that nurses from the so-called training schools which gave short courses of lectures and but little practical training were not recognized by the College

of Physicians, which has an office open day and night for the supplying of trained nurses to private cases.

The Philadelphia Medical Journal.—With the opening of the New Year, Dr. George M. Gould will retire from the editorial management of the *Philadelphia Medical Journal*, and the duties he has so ably carried on will be assumed by Dr. John Hendrie Lloyd and Dr. Julius L. Salinger. Relief from a threatened financial embarrassment has been averted, through a change of ownership, Mr. Morwitz, the publisher of *The German Demokrat* of Philadelphia, now controlling the majority interest. It is rumored that Dr. Gould will be connected with a new periodical enterprise. Should such be the case, Dr. Gould will undoubtedly command the good wishes of the profession at large.

Early Restoration of Function in Sutured Nerve.—Dr. Ernest La Place reports a case of practically immediate restoration of function following suture of the ulnar nerve. The nerve had been severed for a period of sixteen months. When the ends were prepared for suturing a distance of one and three-quarter inches intervened, but this was overcome by stretching. The ends were carefully apposed and a large number of sutures inserted. On the morning following the operation it was noticed that the boy had perfect motion of the hand. As no observation was made earlier it is not known if motion was present immediately after the operation. Sensation in the fingers is curiously altered in that pricking at one part is felt in another. This is supposed to be due to the fact that the corresponding proximal and distal ends of the fibers were not joined. The case presents points in support of the theory of the electrical nature of nerve force.

Medicine and Surgery of the Coming Century.—Drs. H. C. Wood and J. William White, in articles recently written for a local paper, give their views regarding the future of medicine and surgery. Dr. Wood, after stating the inability of man to foretell what the coming century will bring forth, says, "Only this seems probable, namely, an enormous increase of our knowledge of what may be considered the natural remedies for disease. Very many diseases produce within the human body the antidote which enables the forces of the system, if they do triumph, to achieve their victory over the forces of disease. Most, if not all, contagious diseases seem to leave behind them in their victim some substance which protects him in the future, more or less imperfectly, from the same disease. The approaching rewards of medical investigation which shall be of the most value to mankind will probably lie in this province of study. We now treat most contagious diseases by modifying the symptoms and trying to keep the patient alive until Nature shall have completed her processes and cured the disease. It may well be that in the future the physician will have the natural antidote in his hands and put an end at once to the disease; or, perchance, by the previous use of the antidote he may prevent the attack of the disease—vaccinating, so to speak, the patient against all contagious diseases as he does now against smallpox. Whether man shall eventually reach the condition in which the doctor shall be eliminated from the body politic because his occupation has been destroyed by the removal of disease, who can tell?"

Dr. White states that so great an advance has been made during the century that the surgery of 1800 was more closely allied to that of Hippocrates that to the surgery of 1900. Dr. White is not pessimistic as was Mr. Lyme when he told Lord Lister in his early days to remain in Edinburgh, remarking at the same time that it really seemed as though there were not much left to do in the way of advancing surgical science. Looking forward is speculation, but "it seems safe, however, to affirm that before the coming century is very old many conditions now beyond the reach of surgery will come well within its field for either prevention or cure. The discovery of the cause of cancer will be made and will be followed by greatly improved methods of treatment. As we already know the cause of tuberculosis, its cure also should soon be possible in infinitely more cases than at present. Blood-poisoning in its many forms, already through antisepsis so greatly diminished in number and severity, should with the advance of the serum treatment, and of other yet-to-be-discovered methods, almost disappear. Lockjaw should be wiped off the list of surgical complications. All the infectious diseases now so fertile in producing conditions requiring surgical intervention will almost certainly be done away with by preventive inoculation, or will be easily and rapidly cured by the use of the respective antitoxins. New anesthetics, new antiseptics, new means of modifying vital processes and destroying harmful intruders into the living organism may confidently be anticipated. The problems of life are being investigated in ways which may at any moment result in a revolution in all our methods of approaching questions involving living matter. It is not impossible that both the medicine and the surgery of the future will deal directly with the individual cells, the aggregation of which make up all living organisms. It is not rash in the present condition of experimental and inductive science to predict that the advances in surgery during the twentieth century will outstrip even the epoch-making discoveries of the nineteenth."

CHICAGO.

Evanston Hospital.—Plans for improvements and additions to the Evanston Hospital, which will require an outlay of nearly $50,000, have just been completed. The plans include the erection of the new Herman D. Cable Memorial Building, a new isolation hospital, a boiler-house, and improvements to the present buildings. The

Cable Memorial Building will be a handsome four-story structure of brick and terra-cotta.

Prevalence of Influenza.—Eight deaths have been reported this month from influenza. One physician reports that he has had 35 cases of the malady within ten days; another that he has treated 30 cases within a week.

Prevalence of Typhoid Fever in St. Luke's Hospital.—Within the last three weeks a dozen or more cases of typhoid fever have developed among the nurses, physicians and employees of this hospital. The hospital authorities are at a loss to account for the outbreak. Every resource has been exhausted to discover the cause of infection, but without success.

Obituary.—Dr. Ephraim Ingals, one of the pioneer physicians of Chicago, died on the morning of December 18th, at the age of seventy-eight years. Death was due to heart failure. For many years Dr. Ingals was closely associated with the development of higher medical education in Chicago, both as a lecturer in and contributor to the medical institutions of the city. At the time of the affiliation of Rush Medical College with the University of Chicago he gave $25,000 to aid in paying off the college debt and to found a Chair of Therapeutics and Preventive Medicine. He also gave $10,000 to the Northwestern University Medical School for the equipment of its laboratories.

New Dormitory of Provident Hospital.—The beautiful dormitory of this hospital, built to give colored women facilities for becoming trained nurses, was dedicated December 21st. It is a model of all that is convenient and comfortable for the training of nurses. It is complete in every respect from the diet kitchens in the basement to the dormitories and study rooms on the third and fourth floors. Although adjoining the hospital and opening into it, the hall is entirely separate, and gives perfect quiet and freedom to the nurses when not on duty, which in their work is so necessary to enable them to endure the severe strain. It was a year ago that Nathan N. Freer donated $12,000 for the building of Esther Freer Home in memory of his mother. Realizing the general advance in the cost of building and building materials, the donor enlarged his original gift by adding $3520 to cover the cost of construction, and $2595 to meet the cost of furnishings.

Regulations for Lodging-Houses.—Dr. M. Meyerovitz, Chairman of the Committee on Lodging-Houses and Sanitation of the State Board of Health, recommends the following regulations for lodging-houses: Mattresses must be made of washable rubber. Houses must be fumigated at least once a week. Better toilet arrangements must be provided. Each lodging-house shall have a temporary isolation room for use in case of an outbreak of a communicable disease, and before the local health board is able to act.

Illinois Northern Hospital.—The new infirmary at this institution for the insane, located at Elgin, was recently opened, the cost of its erection being $38,000. The building will accommodate 110 patients.

Sentence of James Armstrong.—Judge Kohlsaat has imposed a sentence of one year in jail and a fine of $500 on James Armstrong, President of the Metropolitan Medical College. The defendant was convicted recently of using the mails to defraud in connection with a "diploma mill." Sentence against Thomas Armstrong, who was convicted, and John H. Randall, who pleaded guilty to the same offense, will be passed at the next term of court in March. James Armstrong made a hard fight, and he now threatens to prolong the legal battle in the higher federal courts. The Armstrongs first began business in 1895 with the "Illinois Health University." This was a "diploma mill" on a small scale, and the Illinois State Board of Health, through its secretary, soon closed the doors of the bogus institution. Then the charter for the Independent Medical College was used. The charter of the college was revoked some years ago. The same kind of "graduating" work was continued under the name of the Metropolitan Medical College, although a restraining order was issued in the State court against the officials doing business under this charter.

GENERAL.

Typhoid at Galveston.—Dr. Charles T. Peckham, Surgeon of the United States Marine Hospital Service, stationed at Galveston, who has been in charge of the Marine Hospital work since the storm, confirms the reports from Galveston that typhoid fever is raging on the island. He estimates that there are now between 400 and 500 cases in the city. He said: "I think the disease is directly traceable to the cistern water. We have two kinds of water, cistern and the Alta Loma water, which is piped some fifteen miles. A layer of mud was spread all over Galveston after the storm, which soon dried, and left a layer of the baked filth that had come up from the sewers and the drains. The wind blew the dust over the city and into the tops of the cisterns. In that way we think the disease originated."

Yellow Fever and Mosquitoes.—Press reports say that a number of experiments are being tried at Marianao to test the Finlay mosquito-yellow-fever theory. Soldiers are said to be sleeping in clothing used by infected patients, but are protecting themselves from mosquito bites. The reports thus far are said to be favorable.

Influenza in St. Petersburg.—The influenza epidemic in St. Petersburg is so severe that the mortality returns for the last week have been the highest for a decade. The disease has swept the city, and every office has vacant desks, and every

private table has or has had vacant chairs. The whole city has been swept. The weather is conducive to the spread of the disorder, being changeable, with snow and slush alternating.

Bubonic Plague in San Francisco.—In a report to Gov. Sayers December 20th, on the bubonic plague situation at San Francisco, State Health Officer W. F. Blunt says that the disease continues to spread there and that twenty-two cases are known to have occurred since March 6, 1900. He charges that the press and certain other interests in San Francisco are making strenuous efforts to suppress the fact of the existence of the disease there. He quotes Dr. J. J. Kinyoun, Federal Quarantine Officer at San Francisco, as reporting officially: "I would state that it is my belief that the area of infection is gradually growing wider, so that now there are only three blocks of the Chinese quarter proper in which there has not occurred since March last a case of plague. The conditions which will obtain in the next six months will be, in my opinion, conducive to a further spread of the disease. I believe other cases occurring in San Francisco are being reported under another name."

Illegal Practice in Virginia.—Great difficulty is experienced by the medical profession in the State of Virginia in preventing the illegal practice of medicine in that Commonwealth. The responsibility rests chiefly with the officers whose duty it is to enforce the laws on the subject. The offence of practising without a certificate from the Medical Examining Board of the State is a misdemeanor which can be prosecuted only before a Justice of the Peace. The Secretary of the State Board has publicly asserted that these magistrates, for the most part, do not sympathize with the law against unlicensed practitioners and hence that many well-founded prosecutions fail. All sorts of subterfuges are employed to evade the statute, as in the case of one quack who asserted that the charges which he made to his patients were not for his services as a doctor, but merely for the use of his horse and buggy. The Medical Society of Virginia is endeavoring to put an end to this state of things by securing an amendment to the existing law or its better enforcement.

Smallpox Situation in the United States.—During the fiscal year ended June 30, 1900, 14,998 cases of smallpox, with 731 deaths, in 44 States and Territories, were reported. The Surgeon-General reports that the disease has been of a mild character, the death-rate being less than 5 per cent. This disease is considered one which it is the duty of local authorities to suppress, but, following out the plan heretofore adopted by the Service, the assistance rendered to State and local boards of health has been by the distribution of publications and the detail of officers to make investigations, and personally to explain the methods to be adopted in the suppression of the disease in communities requesting such advice.

CORRESPONDENCE.

THE HALL OF FAME.

To the Editor of the MEDICAL NEWS:

DEAR SIR: Among the distinguished Americans already chosen for the Hall of Fame of New York University, physicians are conspicuous for their absence. Surely this is not because America has produced no physicians whose work would compare favorably with that of the men who have been selected. Perhaps it is because the physician is content to carry on his pain-destroying and life-saving efforts without having the same noised abroad, and himself applauded by the populace. Certainly he deserves all the more praise for displaying a modest, noble spirit.

It is too late to contend for a place among the first thirty Immortals, but we should see to it that the profession is represented among the next number of representatives chosen.

France has already honored her Pasteur and England her Simpson; why should not America honor Dr. Cranford W. Long, the discoverer of the pain-dispelling power of ether? All the more honor is due him since he made that discovery before Sir J. Y. Simpson discovered the similar property of chloroform.

A. JUDSON CHALKLEY, A.M.,
Miami Medical College.

Cincinnati, O., November 30, 1900.

THE NEW YORK STATE TUBERCULOSIS HOSPITAL.

To the Editor of the MEDICAL NEWS:

DEAR SIR: It is a cause for regret to the friends of the antituberculosis movement in the State of New York that difficulty should be encountered in the selection of a site for the first State Hospital. One would suppose that certain broad principles underlying the modern sanatorium treatment of this disease had been settled by the experience and discussion of the past fifty years. One would also suppose that these principles were universally applicable whether the sanatorium were located in England, Germany, or in the State of New York. No country in the world, so far as I know, has deliberately selected a site within one or two miles of a State prison and an asylum for insane convicts, as admirably suited to the treatment of tuberculosis. New York State is the first civilized community that is considering the advisability of taking such a step in the selection of Dannemora, Clinton County.

It would appear to me that such a step would be inexpedient, unless there were absolutely no other place available in the Adirondacks, to which region the Trustees are, by law, limited in their choice, or unless the spot selected with this incubus of an insane and convict population presented special climatic or other advantages. The first of these alternative suppositions may be dis-

missed because, as a matter of fact, the Trustees have inspected more than twenty other sites, any one of which would be possible. A recent visit to Dannemora, an inspection of the site offered at that place, conversation with the prison physician, a study of his plea made in favor of Dannemora, at the joint hearing before the State Board of Health and the Forest Preserve Commission, together with a study of the annual reports of the New York Weather Bureau, have convinced me that the second supposition may also be dismissed. A good deal of the medical evidence offered to prove the special advantages for this site has no bearing on the question, and would not appeal to a jury of physicians as entitling it to preference over other places. I refer especially to the pneumonia, typhoid, and tuberculosis statistics. The statistics of the mean temperature and the mean annual rainfall are at variance with the official reports of the Weather Bureau of the last ten years. The entire plea suggests the ease with which any place may be made to blossom out as a veritable Garden of Eden for the unfortunate consumptive, if sufficiently watered and fertilized by local enthusiasm and the imagination of its promoters. In spite of the cheerless and even depressing influence of the Dannemora surroundings, as compared with other places in theAdirondacks, nobody will deny that it offers some of the requirements laid down by the Trustees for the selection of a site; it has proper elevation, exposure, and water supply. Nor will anybody deny that incipient tuberculosis may be cured at Dannemora—or indeed at any place in the Adirondacks—still, no one would think of erecting a private sanatorium there, and it is the plain duty of the Trustees to act for their poorer fellow-citizens with the same discriminating judgment.

Let us not be blinded to the fact that the main arguments in favor of Dannemora are the gift of the land and the labor for the construction of the buildings. This is tempting bait. Yet it is to be hoped that the Trustees will not yield to it. The natural and commendatory desire on the part of the prison officials to secure labor for their convicts should not lead the Trustees to subordinate the interests of the consumptive poor to those of the convicts.

This is to be only the second State Hospital for incipient consumptives in this country, and upon its success may depend the fortunes of the whole movement in this and other States. Patients are to go there voluntarily, and much, perhaps all, depends upon getting them there early; there ought to be no prejudice in their minds against the place and its associations; no risks should be taken in the choice of site that would entail hesitancy on the part of the patient. Furthermore, be it remembered that the incipient consumptive is not a helpless invalid easily controlled through his very helplessness, but well enough to assert his own individual prejudices.

At some future time, when the movement in this State is itself no longer in the incipient stage and when the advantages of early sanatorium treatment of consumption have won their way into the hearts of our tenement-house population, the objections against Dannemora may weigh less in the balance, but for the present, at least, Dannemora ought to be eliminated from the list of available sites. Alfred Meyer, M.D.

801 Madison Avenue, New York, December 18, 1900.

OUR LONDON LETTER.

[From Our Special Correspondent.]

London, December 15, 1900.

ESTABLISHMENT OF AN EPILEPTIC COLONY IN CHESHIRE—OPENING OF CANCER RESEARCH LABORATORIES AT THE MIDDLESEX HOSPITAL—MAJOR ROSS ON THE PREVENTION OF MALARIA.

Preparations for the establishment of an Epileptic Colony in Cheshire are making rapid progress. The scheme owes its existence to a munificent gift of $400,000 of the David Lewis Trustees. About 400 acres of land have been purchased at a pleasant and healthy site. The equipment will be on a generous scale and when the scheme is completed there will be no institution in England equal to it. The area of the buildings covers 3000 yards and the site is to be laid out in a beautiful park. The remainder of the estate will be available for recreation, and for gardening and farming pursuits, in which the inhabitants of the colony will employ a portion of their time. They will live in detached homes in the form of two-story dwellings, some accommodating twenty, others twenty-four, inmates. This arrangement possesses great advantages over the plan of one large residence for the whole of the patients and is a feature to be commended. There will also be an infirmary, a recreation hall, and workshops. It is estimated that the population of Manchester and Salford (for which this colony is principally available) comprises 1100 epileptics. Probably 300 will be accommodated. They will grow most of their own food, look after poultry and cattle and perform farm work in general.

The opening of cancer research laboratories marks a new departure at the Middlesex Hospital which it is hoped will assist in dealing with the disease which next to tuberculosis is the most fatal to mankind. The unsolved and apparently insoluble problem of the origin of cancer will be systematically attacked. There are special reasons why the work should be undertaken here. Of the great London hospitals, the Middlesex alone affords a refuge to inoperable cases of cancer and a handsome block of wards was completed early this year for the reception of those who can no longer hope for any further relief from the surgeon. Some sixty of these unfortunate patients are constantly within the walls. The duty of investigating the causation of cancer and thus laying the foundation-stone of its treatment was specially laid on the hospital by several

of its earlier benefactors. So long ago as 1791 the original founder of the cancer wards, Mr. Samuel Whitbread, gave the hospital the sum of £4000 with the specific instructions that the money should be applied to "the relief of persons affected with cancer and the investigation of a complaint which, though extremely common, is, both with regard to its natural history and cure, but imperfectly known." Throughout the century the wishes of the charitable founders have been carried out, but their hope has not been realized. The patients have received every possible help in alleviating their "dreadful disorder," but the cause remains unknown.

Major Ross, whose investigations in malaria are so well known, read a paper on "Malaria and Mosquitoes," at a meeting of the Society of Arts. He said he believed that it is chiefly in consequence of the disease that civilization does not progress in the tropics as in temperate climates. West Africa, a rich country within a few days' sail of England, is practically a wilderness. Our colonies are in fact cemeteries. He regretted that the British nation is making no serious effort to combat malaria. The hypothesis that malaria is caused by the bite of the Anopheles suits all the facts. Both occur in warm climates, prevail during summer and the rainy season, are connected with stagnant water and rank vegetation, attach themselves to valley and village, and are enormously prevalent in the poorer dwellings of natives. The time is now ripe for a movement against malaria. The prophylactic use of quinine, the use of mosquito nets and window screens, and the destruction of larvæ around the house, should be attended to in every malarious place. He still adheres to the method proposed by him to the Indian Government nearly two years ago—careful surface drainage. He has never said it would be possible to exterminate mosquitoes throughout Africa. He has always referred expressly to large towns.

PENETRATING GUNSHOT WOUNDS OF THE CRANIUM —AMPUTATION OF GRITTI—OSTEOPLASTIC OPERATIONS AT THE KNEE—PULMONARY EMBOLISM AND ITS RELATION TO PHLEBITIS OF THE EXTREMITIES—BILIARY DIATHESIS AND HEPATISM.

Walther, at the Société de Chirurgie de Paris, Nov. 7, 1900, in behalf of Morestin reported the details of an observation of penetrating gunshot wound of the cranium, treated successfully by trephining, exploration and extraction of the bullet. The thirty-year-old patient, who had attempted suicide, presented three wounds in the right temporal region. One projectile had followed an entirely superficial course; another was lodged in the bony wall of the cranium from which it was readily disengaged; and the last had penetrated the skull. Notwithstanding the absence of cerebral signs, the skull was trephined, the torn dura mater lifted up and the bullet found with the probe at only a slight depth very fortunately. It was easily removed and prompt uncomplicated recovery followed.

Reynier believed that Morestin was in duty bound to have made the exact diagnosis of penetration first of all, by means of the apparatus of Contremoulin, for instance. Not in every case does direct primary intervention result as happily as in this. For example, in a recent case of his own, by the method of Contremoulin he succeeded in locating in the right hemisphere near the surface a ball which had traversed the brain from the left side. It is self-evident how fruitless would have been all attempts at access to it from the side of penetration.

Delens eighteen months ago had the following experience: A ball had penetrated the supra-orbital region; upon exploration with the probe it seemed to have passed upward and inward. Radiography, however, fixed its situation in the occipital region. From this he argued that in the presence of any penetrating gunshot wound of the skull, the surgeon should first of all resort to radioscopic examination before intervening in any other manner.

Reclus added that it is absolutely necessary to do a primary exploration for the purpose of enlarging the bone wound, removing carefully spicules of bone, pieces of hat, hair and bullet, and other possible foreign substances carried in by the ball, of disinfecting and draining at least the mouth of the wound and membranes of the brain.

Quenu disagreed with all the preceding speakers by stating that in his experience and opinion the bullet is a dangerous foreign body usually septic. He therefore believes that to the primary interference advocated by Reclus should be added a gentle, but thorough, probing for the ball. The frequency with which it lies near the surface at the point of entrance makes immediate primary removal a safe rule, with the advantage of disinfection and drainage of the entire route it has taken.

Tuffier, although he supported the diagnostic value of radioscopy in such cases, stated that even it might prove a dangerous disturbance of the patient in certain cases, because the changes of position, which are so material in order to obtain the proper views of the ball, might renew intracerebral hemorrhage. Consequently, he felt that all immediate molestation of the patient should be delayed for a short time.

Potherat, continuing the same subject, at the session of November 14th, detailed a case in which the cranium had been penetrated by a projectile of very small caliber. The conduct of the surgeon had been possibly too hesitating. In the month of December, 1899, he was called to see the victim of a hunting accident, who presented in the right temporal region three small wounds.

After being unconscious for four hours the patient recovered with imperfect speech; and a few days later suffered briefly from fever, right hemiplegia and aphasia. All were due no doubt to the cerebral lesion caused by the penetration of one of the shot. At the autopsy a perforation was found of one of the small shot through the base of the skull and an abscess over the convolution of Broca. The projectile was found only after filtration of the cerebral substance.

Lejars reported for Szczypiorski (Mont-Saint-Martin) three cases of the amputation of Gritti for traumatism of the leg. In the first patient a crushing accident had almost entirely detached the leg and primary amputation was resorted to. In the other cases the amputation was secondary. For one of these patients, also the victim of a crushing accident, he did the amputation at the site of election. Gangrene of the stump set in. In the other case he followed conservative therapeutic measures, but secondary hemorrhage, gangrene of the damaged member and abscess in the popliteal space appeared, which necessitated sacrificing the leg. The amputation of Gritti is little in favor in France, because it so often gives a stump upon which the patient cannot support himself. The cause of the difficulty is usually a secondary late displacement of the patella, which, by imperfect apposition at the time of operation, does not become firmly attached to the stump of the femur. On the other hand, many advantages are offered and usually obtained through the osteoplastic technic by which the sawn surface of the patella is at once fixed to the end of the femur. In these cases lasting adhesion between the two bones is usually established from the outset.

Merklen, at the Société Médicale des Hopitaux de Paris, November 9th, gave his observations on pulmonary embolism, secondary to phlebitis of the lower extremities. In his first case a puerperal phlebitis with embolism at the invasion, a long febrile state and later progressive involvement of both lower extremities resulted fatally within a few hours from asphyxia due to pulmonary embolism about twenty-three days after the appearance of venous symptoms. His second patient suffered death in the same way about five weeks after the onset of a phlebitis secondary to a large hematoma of the calf caused by a crush. Like his first patient, this one had early embolism in the veins with pulmonary congestion. The course of both was simple, but their outcome grave. A very moderate fever, manifested by an evening rise to only 37.8° C. and by a disturbed digestion, had been present at first and recurred eleven days before death. Emboli due to such phlebites during their onset are with rare exceptions benign, because they are due to the migration of clots, small, still friable and little adherent, developed in the venules. The late emboli on the contrary are grave and often mortal, because they consist of large coagulations separated from the thrombotic mass in a large venous trunk. Most authors attribute the majority of these emboli to the breaking off of the free extremity or center of the thrombus before this is completely organized. This explanation holds only if under some particular condition the process of organization is not perfect after the ordinary delay. There is another more rational hypothesis in the view of the author. These late emboli are more probably due to secondary, delayed exacerbations of the latent phlebitis in the large vein, followed by the formation of new large clots not immediately adherent and also easily movable like those of any phlebitis at its onset. Thus the pathogenesis of these late emboli is the same as of early emboli, because they are the simple result of practically a new inflammation of the veins which may manifest itself only with slight fever. In the treatment, therefore, it is necessary to take the temperature of patients most carefully during phlebitis and to insist on complete rest in bed for several weeks after absolute apyrexia. Only then may the affection of the veins be considered ended. This conclusion, moreover, conforms with the rule of Pinard, who keeps in bed for one month after the last elevation of temperature all cases of childbirth complicated with phlegmasia. The prognosis is generally favorable in phlebitis with early embolism, except in the latent affection of the large veins with late exacerbations, especially in light prolonged infections, in virtue of their evident effect in causing mortal emboli. The real method of such clot mobility is as little understood as the formation of the clot itself within the vein. It is hardly likely that a clot once adherent to the wall of the vein, organized and contracted, should become detached. The hypothesis of new formations upon it and their migration is much more probable. In literature the thesis of De Brun states that the latest appearance of such an embolism was three months after the formation of the thrombosis. Unfortunately, nothing is said by this author as to the presence or absence of a latent phlebitis during this long interval. Phlegmasia of childbirth is most apt to cause the precocious benign embolism, but is singularly unlikely to initiate fatality in this way, since Pinard has found but four such cases in ten years at the clinic in Baudelocque. A valuable distinction, if it were practicable clinically, would be one between resolving and obliterating phlebitis.

Rendu disagreed with the hypothesis of the cause of these late emboli. Admitting their usual gravity, he said, they are due to fragments of the original thrombotic mass which begins to disintegrate about three weeks after the beginning of symptoms.

Triboulet felt that the most important point to establish is, in view of their prognosis, a distinction clinically between embolism precocious, apyretic, without apparent phlebitis, often present at about the eighth day after childbirth and usually of a favorable termination, on the one hand,

and, on the other hand, phlebitis with fever, successive exacerbations, various degrees of infectiousness and very commonly with fatal issue from migrating clots.

Launois called attention to the researches of Cornil as to the histology of such thrombotic masses. After a variable time he found that they are invaded by embryonal connective tissue cells, which proceed from the wall of the vein, interlace, and form a network entangling in its meshes the different elements of the clot into a compact mass, thus obliterating more or less completely the lumen of the vessel. One understands, therefore, the persistence of edema for a long time after the cure of the phlebitis. Very commonly this late edema is due, not only to alterations in the venous and lymphatic circulation, but also to local trophic changes.

Barth said that sometimes there exists merely gross obstruction of the vein and sometimes organization of the clot, by the process discovered by Cornil. The subsequent history of these cases makes it likely that when edema persists this condition obtains.

Hallopeau reported a case of late fatal embolism six months after the original phlebitis.

Vaquez, at the session of November 16th, resumed the same subject and advanced the following theory: The so-called precocious emboli are due to the disintegration of a clot which in its essence, according to Cornil and Marie, has little tendency toward organization, belonging really to that phase of phlebitis which one might call the *prcobliterating period,* but often going on to the existence of a *latent phlebitis with embolism.* Such precocious emboli are always small fragments, therefore rarely dangerous unless infectious. On the other hand, the late emboli are large masses of clot floating about, detached because originally their adhesion to the venous wall was insufficient, and often deadly from their size alone. Unfortunately, this exact anatomopathological classification cannot be clinically distinguished. In fact, it may be that, through successive attacks of phlebitis, precocious benign fragmentary emboli form in fifteen, twenty, thirty days or even later, while, on the other hand, an embolic mass may coincide with a total obliteration of the vessel only a few days after the appearance of the phlebitis. His own rule in treating these cases is the following: Stiffness of joints and atrophy of muscles, with later contractures, may follow too prolonged immobilization; therefore, to avoid these untoward consequences, for only three weeks after the onset of phlebitis in the large veins of the inferior extremity, especially if bilateral, is absolute immobilization carried out by some of the well-known gutter-splints. After this time, if the large trunks have ceased to be tender, if there have been no rises of temperature, and if the edema is frankly decreasing, he carries out maneuvers aimed to favor the collateral venous circulation and consisting only in superficial effleurage of the skin and in partial passive movements of the toes and foot. Later, at the twenty-seventh to the thirty-fifth day, the muscles are massaged, the joints more actively moved and the venous trunks left as far as possible undisturbed. The patient is allowed to move about in bed a little, but not to flex his trunk. Following the thirty-fifth day this treatment becomes gradually more and more pronounced, the patient is allowed to lift himself in bed and, finally, to get up out of it; he is not allowed to use elastic stockings or supports of any kind. A light gauze bandage may, however, be applied. Complete cure is usually present by the fiftieth day under this management. If relapses occur, characterized by elevation of temperature, local tenderness and recrudescence of the edema, he resorts immediately to the same processes *seriatim,* beginning with the immobilization. Replying to an inquiry from Merklen as to the usual status of the solid clot causing the late massive emboli, he stated that commonly sufficient adhesion occurs between the wall of the vessel and the mass. It is precisely when such are not formed at all, or imperfectly, that separation transpires. However complete relief of obstruction of the vein in this period, as claimed by Rendu in the last session, is uncommon. When edema promptly disappears it is due to the fact that collateral circulation, at first impaired, is restored, rather than to the fact that the main channel is partially or entirely opened.

Glenard read notes on cases, occurring during the past ten years, of the so-called hepatism of Gilbert and Lereboullet, described by them in the last session. These included various states of dyspepsia, chlorosis, etc. All were apparently of hepatic origin, yielding to appropriate treatment of the liver, and assignable to the category of these two authors as expressions of biliary diathesis or hepatism.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held November 19, 1900.

The President, Parker Syms, M.D., in the Chair.

General Septic Peritonitis.—Dr. Irving S. Haynes said that for the diagnosis of septic peritonitis the quality of the pulse is of more importance than its frequency. At the beginning the pulse is apt to be thin, thready, distant, easily compressible, and the arteries easily emptied under the finger. The reason for this is that the blood of the system is gathered to a large extent in the dilated blood-vessels of the abdomen. The intense inflammatory reaction leads to a reflex relaxation of all blood-vessel in the abdominal cavity and these are capable of containing, when dilated, most of the blood of the body. Only later in the peritonitis does the hard, wiry pulse usually

set down as characteristic of peritonitis develop. When all cases of peritonitis were inevitably fatal this character of the pulse preceding the fatal termination was a pathognomonic sign of the condition. Patients with peritonitis, seen early enough for operation and recovery, in Dr. Haynes' experience, had an average pulse-rate not much above a hundred. In a series of fatal cases the pulse-rate averaged 130. In cases of localized peritonitis or inflammation of the intestine the hard wiry pulse considered pathognomonic of peritonitis by the older physicians frequently occurred. Its prognostic significance is not as absolutely unfavorable as it was formerly thought.

Fever.—As a rule the fever of peritonitis does not run very high. General septic peritonitis may occasion a rise of temperature to 102° F. It may not run above 101° F. The average is rather under than over 103° F. and only exceptionally does a temperature of 104° F. occur. Of more diagnostic and prognostic significance than either the pulse or the temperature is the appearance of the patient. The face is drawn and frightened-looking, even though the patient may not feel fear. There is a tenseness about every muscle that reminds one of the corresponding condition in the abdominal muscles. It is as if the whole system realized the danger and used the ordinary modes of expression to make clear its unconscious feeling of danger.

Prognosis.—General peritonitis patients always die if not operated upon; they may die even after operation. It is well worth the while to give then the only chance for their life no matter how unpromising the condition. If the operation can be performed on the average not longer than four hours after the development of the peritonitis the prognosis is good. In Dr. Haynes' experience recoveries have taken place only in patients who were operated on in from two to seven hours after the onset of symptoms. Some patients were operated on when symptoms had existed longer than this, but they invariably died. Should apparently moribund patients be operated on? Many surgeons refuse to operate under such conditions, because, they argue, it serves no good purpose, only creates prejudice against abdominal surgery and makes the statistics of these operations appear worse than they really are. It is not easy to decide, however, just when a case passes from the operable into the inoperable stage of the disease. The patient will surely die without an operation, but he may survive even if desperately ill if operated upon. Dr. Haynes recently performed an operation contrary to the advice of two consultants, who considered the case hopeless, and to the surprise of all recovery took place.

Early Diagnosis and Statistics.—The important condition for success in the operation is early diagnosis of peritonitis. The first symptoms are pain in the abdomen which is sudden, continuous and then spreading, followed by collapse and the symptoms of shock. When these symptoms occur it is not only useless but criminal to delay. The patient's only hope lies in operation and the sooner this is done the more are the chances of recovery. Forty-six per cent. of Dr. Haynes' cases recovered. At least three of the fatal cases, however, were operated on at a time when hope was practically out of the question. One of the cases had been suffering from peritonitis, due to a ruptured peritoneal ulcer, for twenty-seven hours when the operation was done. In another the symptoms had persisted for twenty-four hours and the peritonitis was caused by a rupture of the intestine through a cancerous ulcer. In a third fatal case rupture of the appendix occurred the day before the operation was undertaken.

Technic.—One of the most important considerations with regard to operation for peritonitis is the location of the incision. If it is suspected that rupture of the stomach or of the appendix has occurred, of course, the position of the incision would be fixed by this fact. If, however, there are no localizing symptoms, the incision should be made in the median line just below the umbilicus. This incision can be enlarged upward or downward as may be necessary. In penetrating wounds of the abdomen followed by peritonitis the original wound should be enlarged. After the incision is made and the peritoneum has been opened the character of the exudate in the peritoneum will furnish information as to the point of origin of the peritonitis. If particles of food are seen, there has been a rupture of the stomach or duodenum. If the pus has a distinctly fecal odor, there has probably been a rupture of the appendix. If there is bile in the peritoneal cavity, it points to a pathological condition of the bile-tract, while if in females the pus wells up from the pelvis, yet has no fecal odor, rupture of a pus tube is the lesion.

Abdominal Flushing.—The abdomen should be thoroughly flushed out with normal salt solution. The tube that conveys the solution into the abdominal cavity should be carried to every part of the peritoneal cavity. This should be done before looking for the lesion. Sponging has been recommended, but it is too slow and not every part of the peritoneal cavity can be thus reached. If the sponge is not used very gently or if it is at all rough in texture, the delicate peritoneal covering of the intestine is injured and adhesions will form. Evisceration acts on the patient as would a blow on the solar plexus. The resulting shock is serious, persistent and is felt at once. If the intestinal coils are much distended an incision should be made in them at a point opposite the mesenteric attachment. As the gas escapes from them care should be taken that none of the intestinal contents find their way into the abdominal cavity. Hydrogen peroxide in full strength may be used without danger in the abdominal cavity. Its use, however, does not seem advisable. Flushing appears to be the best way of cleaning the soiled peritoneum.

Drainage.—The best form of drainage is iodoform gauze wrapped in rubber tissue, which pre-

vents adhesions and facilitates the changing of the dressing. If the purulent material within the abdomen is thick, a tube should be used as well as the wick of gauze. If the gauze is left long enough to hang down somewhat at the patient's side, it assists in the removal of purulent matter. The dressing should be frequently changed. Some operators prefer, if possible, to close up the abdomen, but this seems inadvisable, because it adds to the risk. Where drainage is used, the abdominal wall will subsequently be weaker than before and a hernia may occur. But a ventral hernia in a living subject is capable of cure. "A beautifully sutured wound in a corpse availeth nothing."

Stimulation During Operation.—Strychnine is very valuable. Care must be taken, however, not to overstimulate. The idea is not to overexcite a weakened organism, nor to whip a frail one into efforts beyond its power, but to lift up the tottering forces. Whiskey may be given almost *ad libitum* with a hypodermic syringe. It takes many a syringeful to affect the ordinarily healthy individual, and still more is needed to favorably affect a weakened patient suffering from an intense toxemia. When the heart is weak the stimulating effect of frequent swallowing must not be forgotten. Spoonfuls of water should be given occasionally and the reflex improvement of the heart's condition through the vagus reflexes will soon be noticed.

Varieties of Septic Peritonitis.—In discussion Dr. Dowd said that septic peritonitis is no longer considered to be the necessarily fatal disease that it was thought. For any instructive consideration of the mortality, its forms must be taken into account. In a certain number of the patients, while there is undoubtedly an inflammatory tendency in the peritoneum, true pus is not present, but only serum. In a second severe type seropus is present. Sometimes this is true, thin pus, in which case the peritonitis is only mild. Some surgeons speak of it as cloudy serum. This frequently produces a decided febrile reaction, but the inflammation is not of a virulent character. In either of these forms of peritonitis a large number of successes follow operation. In a third variety of peritonitis thick pus occurs with shreds of fibrin on the peritoneal surface of the intestine and here and there shut in abscesses. These cases very seldom recover, no matter how thoroughly drained or cleansed. In a certain number of cases there may be thick pus at the site of the original infection and cloudy serum or simple serum in the peritoneal cavity. Most of these cases get well after simple drainage of the original abscess. For true septic peritonitis, however, the best treatment is undoubtedly hot saline solutions used abundantly and as far as possible carried to all parts of the abdomen. During the last ten years we have learned to respect the peritoneum and now realize that there is much less necessity for drainage than was formerly thought. If the abdominal cavity can be thoroughly washed out, peristalsis encouraged and perhaps some portion, at least, of the intestinal contents removed in these cases, there seems no doubt that there will be a decided improvement in the statistics of operation for septic peritonitis.

Character of Infection.—Dr. Benjamin T. Tilton said that many of the cases successfully operated on are true generalized peritonitis, but consist of a series of pus foci here and there, many of the coils of the intestine not being bathed in pus, however. In virulent general peritonitis it is probably impossible to save the patient. Any sign of reaction on the part of the peritoneum against the infection is encouraging and good results will sometimes occur even in most unpromising cases. The hope for the future of peritonitic surgery lies in getting the cases earlier from the general practitioner. The dry method of cleansing the intestine by sponging is of little practical value. Bacteria are left in the peritoneal cavity and injury is inflicted on the intestine by the fiber of even the finest sponge. Drainage should not be depended on as the only hope, but the peritoneum should be trusted more than has been the custom.

Dr. Brothers said that the question of raising the foot of the bed for heart stimulation is important, but it must be remembered that drainage of the peritoneum may be even more important and this can be best accomplished often by raising the head of the bed. As to the relative merits of sponging or flushing, if there is an especially virulent focus of infection, as in wounds of the intestines, this should not be scattered all over the peritoneal cavity by flushing, but local cleansing by sponging will be safest. Only when there is surely generalized peritonitis should flushing of the peritoneal cavity be employed.

Dr. Erdmann said that he has limited the use of flushing more and more of late and has been very well satisfied with the results. There is serious danger that the salt solution will carry infective material beyond the limits of infection at the moment and so prove dangerous. In one case where he employed flushing for peritonitis after a wound in the stomach, the patient died two days later and some spaghetti was found in the lesser peritoneal cavity. Whether this had been carried in by the flushing could not be determined. The anatomical relations of the foramen of Winslow, however, are such that this accident must always be considered possible.

Hot Vaginal Douche.—Dr. James Hawley Burtenshaw said that hot water has been used for pelvic affections almost from time immemorial, yet nothing is less understood than the proper principle on which it should be employed. The abuse of it may do infinite harm. Hot water first dilates and causes congestion. As Dr. Goodell used to say, if a finger be plunged for five minutes into water as hot as can be borne it becomes red and swollen. It would be impossible to remove a ring that slipped off the finger rather easily before. After fifteen minutes, however, the tissues of the finger shrivel and become pale. The second effect is the one sought for when

vaginal douches are employed. On this principle two quarts of water which flow from an ordinary fountain syringe placed three feet above the patient and which will take by actual experiment two minutes to flow will do harm rather than good. It adds to the congestion, intead of relieving it. Four quarts are scarcely better. At least three gallons of water should be used and it should be allowed to flow into the vagina for about fifteen minutes.

Vaginal Douche Technic.—The patient should be instructed to lie flat on her back with hips slightly elevated and the shoulders low. A large douche vessel or a pail of water from which the water flows by siphon action should be employed. The water should be as hot as can be borne and should be at least 107° F. The douche should be taken every day except for the two days before and after menstruation. If the patient has not proper arrangements for taking the douche in bed it may be taken in a bathtub, a Y-tube being used to connect both the faucets and so have the water constantly of the desired temperature. In order to raise the patient's hips a couple of bricks covered with oilcloth or a roll of blanket which will prevent the water from flowing up around the rest of the body should be employed. Dispensary patients are recommended to put two boards over a washtub slightly separated from one another, so as to allow the water after use to flow into the tub.

Indications for the Douche.—All of the congestive conditions of the pelvic organs are benefited by the hot douche. Acute and chronic nephritis, perimetritis, parametritis, ovarian pain subinvolution and leucorrhea. As a rule, the douche should be used without the addition of medicaments. For leucorrhea the following prescription is given:

℞ Alum .....
Zinc sulphate.....
Sodium biborate.....
Carbolic acid.....aa. ʒ j
Water .....ad. ʒ viii

A tablespoonful of this should be added to the last quart of the douche. Bicarbonate of soda, one level teaspoonful to each quart of water, will often be found a useful remedy for milder cases of leucorrhea. As a rule antiseptics should not be used. They are poisonous to the general system and as the result of the macerating action of the large douches much more of these substances are absorbed than might be anticipated. In mucopurulent discharges dilute wood vinegar will sometimes be found of service. Large vaginal injections, it has been demonstrated, reduce the bactericidal power of the fluids of the vagina. They should not be used during pregnancy. It has been recently suggested that a large rectal douche as hot as can be borne and retained as long as possible affects more of the tissues of the pelvis than even the vaginal douche. They are, however, very annoying to patients and the rectum does not stand hot water well.

Constant Douche Temperature.—Dr. J. Riddle Goffe said that an arrangement by which the water for the douche could be taken directly from the hot water faucet is preferable. In this way a constant temperature is secured and the effect is surer. In a douche apparatus the water has time to cool considerably during the fifteen minutes the douching should last. After operations in the vagina the practice of giving a large hot douche undoubtedly does harm. The tissues are made anemic, their vitality is diminished and failure to unite will frequently occur. In undeveloped uteri the effect of the douche is not to produce congestion or stasis of the blood, but stimulation of the uterine circulation. For this purpose large injections are very important.

Douche Contra-Indications.— Dr. F. P. Hammond said that it was the length of time a douche lasted, not the quantity of water used, that should be regulated. With a small perforation of the nozzle of the vaginal syringe a small quantity of water could be made to serve every purpose of the large douche. Anemia constitutes a serious contra-indication to the use of the large vaginal douche, especially if it is accompanied by headache. The excess of blood invited to the pelvis may cause sleeplessness or even collapse. One-fourth to one-third of the blood in the circulation may be drawn to the pelvic tissues and this the anemic cannot stand. Acute salpingitis constitutes another contra-indication, because the warmth and congestion stimulate bacterial growth. Endometritis fungosa or adenosa also contra-indicates the douche, because stimulation is very undesirable in this condition.

BOOK REVIEWS.

Atlas and Epitome of Gynecology. By Dr. Oskar Schaeffer, Privat Docent of Obstetrics and Gynecology in the University of Heidelberg. Authorized Translation from the Second Revised and Enlarged German Edition. Edited by Richard C. Norris, A.M., M.D., Surgeon-in-Charge Preston Retreat, Philadelphia; Gynecologist to the Methodist Episcopal Hospital and to the Philadelphia Hospital, etc. With 207 Colored Illustrations on 90 Plates and 62 Illustrations in the Text. Philadelphia: W. B. Saunders & Company, 1900.

This is a notable addition to the excellent series of hand atlases introduced into this country by the same publisher. Two distinct works really are embodied in the compass of the one book, the set of beautiful reproductions in colors of the original water-color drawings made in the Heidelberg clinic with their descriptive and elucidating text, and a concise exposition of the pathology, diagnosis and treatment of all the commoner gynecological diseases. This latter section is written from a strictly practical standpoint, the more purely theoretical considerations with microscopical and chemical notes being contained in the portion relative to the drawings.

While written by a surgeon the book is a strong plea for conservatism in treatment, an advantage, however, to the general practitioner whose aim is usually in this direction and who will find many useful plans of non-operative therapeusis outlined. For assistance in diagnosis the author has embodied an abundance of differential tables and a large number of colored diagrams give a clear idea of the significance of the various findings obtained by bimanual examination, the sound, etc. The colored plates adequately cover the field and represent all the lesions likely to fall into the hands of the non-specialist and also many of the rarer disorders, while enough cannot be said in praise of their beauty of execution, which is nothing short of marvelous in a book of such moderate price. We know of no other book that from a practical standpoint contains so much useful information on the subject as this one, and cannot recommend it too highly either for students or practitioners.

Diseases of the Chest, Throat and Nasal Cavities, Including Physical Diagnosis and Diseases of the Lungs, Mediastinum, Heart and Aorta, Laryngology and Diseases of the Larynx, Pharynx and Nose and Special Diseases of the Thyroid Gland and Oesophagus. By E. Fletcher Ingals, A.M., M.D., Professor of the Diseases of the Chest, Throat and Nose, Rush Medical College (in affiliation with the University of Chicago); Professor of Rhinology and Laryngology, Chicago Polyclinic, Laryngologist to the St. Joseph's Hospital and to the Presbyterian Hospital, etc. Fourth Edition. With Two Hundred and Fifty-Five Illustrations. New York: William Wood & Co., 1900.

While not in the least deprecating the constantly-growing tendency to specialism or in any way underestimating the benefits accruing from the division of labor that the present breadth of medical science has rendered almost imperative, one cannot help but wonder sometimes what the final result is going to be. The principle is being carried so far, there are wheels within wheels and specialists in specialties with so meticulous a subdivision of knowledge and skill, and subspecialty is being saddled upon specialty with such frequency that the analogy of the lesser fleas upon the little fleas seems painfully lifelike and one trembles for the ultimate *reductio ad absurdum* which apparently is not wholly a danger too remote to be dreaded. And, as a natural sequence of this endless multiplication of interests, comes a corresponding increase in the literature of the science which has been pouring out during the last few years at a geometrical ratio of progression appalling to contemplate. But, in spite of this making of books which is without end, most of them can find but a limited class of readers and by reason of their ultratechnicality are unfit for the every-day usage of the busy general practitioner. It is therefore with unwonted pleasure that one speaks of so thoroughly practical and useful a book as that under discussion. It is the work of a specialist, but a specialist in the broader sense who has known how to broaden his field and consider not the disorders of a single organ or function, but a large and comprehensive group of diseases which are, however, topographically and physiologically so intimately related that they form a closed circle that must be dealt with in its entirety to be satisfactorily handled. Of the specific merits of the book itself it is hardly necessary to speak in detail, the prominence of its author and the fact that this is its fourth edition sufficiently guarantee its value. Such changes as progress in medicine has demanded have been made and new matter and illustrations added, so that the work can in every way be recommended to the practitioner as affording reliable and modern information on the very complex subjects of the etiology, diagnosis and treatment of the lesions of the heart and respiratory system.

Rhinology, Laryngology and Otology and Their Significance in General Medicine. By E. P. Friedrich, M.D., Privat Docent at the University of Leipzig. Authorized Translation from the German, Edited by H. Holbrook Curtis, M.D., of New York. Philadelphia and London: W. B. Saunders & Company, 1900.

In recent years the realization has gradually come that the laryngologist, rhinologist or otologist can only be successful in his chosen profession when he appreciates how much pathological changes in these special organs are dependent on diseased conditions of the general system. On the other hand, the general practitioner has learned that preliminary and pathognomonic symptoms of many constitutional affections are often to be found in the throat, nose and ear. Dr. Friedrich's book presents itself at once as an index of these feelings and as an auxiliary to further mutual helpfulness on the part of specialism and general practice for the diagnosis of general systemic conditions and local symptoms in the upper respiratory tract. The subject is, of course, a very large one, and even Dr. Friedrich's 315 pages fail to do more than treat the salient points. In fact, there is in the book a sense of the compression that has been exercised in making it and one would wish for more detailed information on certain points.

As a rule, the treatment of the subjects selected is at once interesting and suggestive. We are especially glad to notice that American literature has not been neglected in making the book. Some of the articles, as, for instance, that on ictus laryngis occurring in the course of obesity, gout and diabetes, will furnish new matter for thought to most general practitioners. The laryngeal affections of typhoid and scarlet fever and the aural complications of influenza are notably well done. The chapters on affections of the larynx, nose, pharynx and internal ear in nervous diseases are worthy of attentive study in our day when nervous diseases are occupying so much of general attention.

INDEX.

Abdominal incisions, closure of, 162
section, 677
wall, weakness of, in women, 474
Abdominal hysterectomy, 979
